The variation of density with the depth of fill is a subject which Mr. Mullis has treated rather lightly in view of its importance, although there is a dearth of information on this subject. It is reasonable that the density at any depth of a stabilized road-bed should vary as the load above it and inversely as the width of the base. Since the bearing width increases at a greater rate than the depth, appreciable savings in road-bed construction could be obtained by using a less dense stabilization in the wider portions of the fill which make the larger portion of the embankment. Due to the desire to distribute concentrated wheel-loads and cut down the action of capillary water adjacent to wearing surfaces, it is naturally desirable to require the most rigid control over stabilization in the first few feet below the surface course. This region, being the most exposed and least confined portion of the road-bed, should be the most dense. However, the depth of this layer of maximum density need not be the same for all conditions. With a protective covering of concrete paving one could quite reasonably expect a satisfactory performance with a high density layer of, say, a 2-ft minimum thickness whereas under a bituminous mat it would obviously be much better to have a minimum depth of 4 ft or 5 ft.

The use of a thin layer of granular stabilization (2 in. to 6 in.) between concrete paving and the high density layer is being studied with a view of decreasing the action of moisture on the bottom surface of the slab. It is expected that the moisture coming through the joints, cracks, and at the sides of slab will spread over a wide area on reaching the granular layer, thus producing a light and uniform percolation downward through the road-bed. In this way the layer will act as an insulator. A secondary effect will be to decrease the bond between the slab surface and road-bed, thus lowering internal stresses in the paving due to temperature changes and creep from hillside location.

Ira B. Mullis,[35] Esq. (by letter).—In this paper a new method is offered for designing road-beds. It follows well-known mechanical laws and the writer applies them in a manner similar to that followed by structural engineers.

The discussers have enhanced the value of many phases of the paper, and especially: (*a*) By contributions of basic data; (*b*) by pointing out certain structural relationships between road-beds and ceramic products; and (*c*) by the presentation and discussion of methods of design. The discussions will be commented upon topically and in the order of their appearance in *Proceedings*.

Method of Approach.—Professor Greaves-Walker states that the investigations are unquestionably along lines that will result in greatly improved road-beds and fills. He also states that in the manufacture of a good ceramic product, and in the making of a good road-bed, there is much common ground. In this connection he also stresses the value of ceramic principles which he believes should be applied to the structural design of road-beds.

Mr. Campen expresses approval of: (*a*) The analysis of the steps involved in consolidating water-soil mixtures; (*b*) the classification for road construction of a number of typical soil deposits; (*c*) the method used for showing the effect of water content on the structural properties of soils; and (*d*) the application of the information in the design of road-beds. Mr. Gray expresses his belief that the paper outlines the broader principles of road-beds in a concise and logical manner and recites his own experience in partial support thereof.

Mr. Turnbull says that the paper presents a clear picture of the functions of a soil in a road-bed, and that it reviews the various states of matter and the manner in which each one influences the action of a soil in the road-bed when placed at varying degrees of compaction. He also states that the definitions of the various characteristics of a soil, as well as the various types, are believed to be especially good. Mr. Myers says the paper is a valuable contribution to the literature on the subject of the design of road-beds and especially so because it is written in terms with which every engineer is already familiar. Mr. Lane states that the writer has raised several open questions and interpreted a great mass of fundamental data, but he does not express any view as to the validity of the interpretations.

Density, Porosity, and Moisture Content.—The density feature of the paper has been discussed at greater or less length by six contributors, and all agree that the strength of a road-bed increases with increasing density. This agreement is reached by a group of engineers representing a varied field of experience and research.

Professor Greaves-Walker says that there is no question about the structural properties of earth masses being enhanced and made more highly resistant to water penetration by increasing their density. Mr. Schofield says that Conclusions (1) and (2), relative to the effect of increasing density on the structural properties of earth masses and the resistance offered to the penetration of water, reached by the writer have been verified by Messrs. Everhart, Austin, and Rueckel.[23] Researches by these gentlemen also show that the effect of de-airing clay bodies (and the consequent reduction of porosity and increase of density) increased plastic strength, the dry transverse strength and modulus of elasticity; and, in all but one case, it caused a marked increase in the water-slaking time of the dry specimens.

Mr. Campen states that resistance to pressure increases with increasing density of earth masses, and shows this relationship in Table 2. Mr. Myers contributes Table 5 which gives a detailed concept of the relationships of density, porosity, and water capacity of certain types of earth. In this table certain relationships appear to be common, if not universal. Of these, the following will be mentioned: (*a*) That the percentage of road-bed pore space filled with water during wet weather is generally high; (*b*) that the largest percentages of moisture are found in road-beds of low density (high porosity); (*c*) that the smallest percentages of moisture are found in road-beds of high density (low porosity); and (*d*) that the percentage of road-bed pore space filled with water appears to be reduced by the presence of considerable quantities of coarse matter, such as sand and gravel.

Mr. Turnbull is in accord with the belief that increasing soil density enhances its structural properties, increases its resistance to the penetration of water, and generally improves its desirability in all respects for road-bed use. However, Mr. Turnbull states that certain soils are known to have more detrimental swelling properties at the higher densities. The writer believes that such detrimental swelling occurs only in rare cases, none of which has come under his observation; and, he also believes that no type of earth can be compacted to an extent which impairs its resistance either to pressure or to weathering. The basis for this belief will now be exemplified by means of the inherent properties of a certain clay when compacted to given densities. The clay selected is a gumbotil listed as Item No. 3, Table 5, by Mr. Myers. The discussion is as follows:

It is assumed that this gumbotil is to be placed in a road-bed in each of two states of compactness. It is also assumed that the magnitude of the compacting energy is ample for producing a density of 2.13 (Column (9)), and a water capacity of 10.3% (Column (16)). It is further assumed that the density required for Section *A* is 2.00, with a moisture content not in excess of 12%, and for Section *B* a density of 1.69, with a moisture content not in excess of 22 per cent.

Under these assumptions, the pore space in Section *A* was reduced so that its water capacity was only 1.7% in excess of that of its approximate shrinkage limit. Moreover, since the hygroscopic coefficient[36] of most clays is about 13%, this would aid in preventing further loss of moisture under field conditions. It will be seen, therefore, that the moisture range of earth in Section *A* is limited on the one hand by its hygroscopic coefficient and on the other hand by the restricted capacity of its pores. The capacity of the mass to shrink or swell, therefore, is reduced to the minimum, and its bearing capacity remains high as long as the mass is protected against weathering.

Section *B* was constructed with a water content of not more than 22% and hence, if it contained that quantity of water, was plastic at that time. Furthermore, regardless of the moisture content during construction, the pore space was such that the mass would become plastic whenever a sufficient quantity of water was available. Therefore, the pores, due to their large volume, would offer little resistance to the penetration of water. Assuming that a given drying would reduce the moisture content of the mass in Section *B* to 12%, which value is equivalent to that of Section *A*, the moisture loss since the time of construction would be 10%—a quantity ample for the development of shrinkage fissures of such size or number as would aid materially in the rapid distribution of water when available.

It may be seen, therefore, that the clay, consolidated as in Section *A*, is in a most favorable condition for resisting the loss of water either by evaporation or percolation. Moreover, since the restricted pore space is nearly filled at all times, the amplitude of moisture change is indeed small. By a similar process of reasoning, it may also be seen that the less compact mass of earth in Section *B* undergoes greater changes in volume and moisture content, and a more rapid loss of density when unprotected from the weather, than does Section *A*.

General Requirements for Density.—Within the decade prior to 1939, the necessity for developing considerable density in road-beds and earth dams had become increasingly apparent, and several standards of density have been set up. In 1932 the writer proposed the use of "standard" density as the ultimate density or ideal to be attained. In 1934 one State with which the writer was associated in Federal-Aid road work specified that road-beds must be compacted to 90% of "standard" density. Other standards of compaction have also become more or less popular, but the writer will discuss only his own unsatisfactory attempt to utilize "standard" density as a standard of compaction. Although this standard is an advance in improving the work, it was found to be unsatisfactory, inasmuch as the pore space at standard density bears no constant relationship to the quantity of water required for the production of critical softening or yield point due to water content. This lack of constancy of relationship may be exemplified by test values from Table 5 and shown in Table 6.

5	17.0	14.7	0.86	31	19.2	20.4	1.06
8	15.7	19.5	1.24	42	13.9	20.5	1.47

Density Below the 2-Ft Level.—Of those who discussed this phase of the paper, the following comments were made: Mr. Campen states that the writer's suggestion that pore space in a road-bed at depths greater than 2 ft below subgrade should not exceed 40% of the volume is reasonable, except when applied to certain types of clay. He also states that locations are to be found where road-beds having a 50% pore space are entirely satisfactory for heavy loads because he believes water can be isolated from them. Mr. Myers states that an upper limit of 40% for pore space at depths of 2 ft below the subgrade seems to be entirely practicable and reasonable.

The writer's reason for suggesting an upper limit of 40% for pore space in a road-bed deeper than 2 ft below subgrade (when a lower percentage is preferable) is a two-fold one: (*a*) It is desirable to keep the cost of compaction as low as possible, but without sacrificing too much strength and durability; and (*b*) on a basis of an absolute density of about 2.65 for the vast majority of road-bed materials and the 40% pore space suggested in the paper, the bulk density would be 1.59 and the water required to fill the pore space would be 25.1% of the dry weight. Furthermore, since many earthy materials do not become plastic with less than 20% to 25% of water, the writer believes, on the basis of test data, that pore space in this part of the road-bed would commonly fail to become filled with water to an extent which would produce a plastic state. However, where conditions or materials are such as would produce instability, the upper limit of the 40% suggested should, of course, be lowered.

Density Above the 2-Ft Level.—Mr. Campen states that there is no doubt in his mind that, if all the soil or soil mixture courses within the upper 2 ft are compacted so as to restrict the water capacity to 70% of their plastic limit, the resistance required will be developed; but he also says that the pore space called for is lower and the thickness is higher than necessary and states his reasons for disagreement. Mr. Turnbull points out the difficulty, or even the impossibility, of compacting certain poorly graded sediments to densities suggested by the writer for use in the upper 2 ft of the road-bed. He also says that it would seem to him that the factor of safety set for the upper 2 ft may be somewhat high; but he admits that, for certain soils, it may be entirely practicable and satisfactory.

Mr. Myers states that, in studies made under his supervision, on stabilized gravel base courses, which had a distribution of particle size and a degree of compaction such that the theoretical water capacity was below the limit suggested by the writer, these base courses did not become less dense or absorb additional moisture when exposed to the conditions existing on the road. He also states that samples taken from bases that contained 8% to 10% of moisture at the time they were constructed were found to contain only 3% to 7% of moisture two years later. Mr. Myers also conducted laboratory studies on the porosity-water content relationship through ten cycles of freezing and thawing, after which it was found that the specimens in which the theoretical water capacity was greater than 70% of the lower plastic limit of the material decreased in density and increased in moisture under the test procedure. Specimens with a theoretical water capacity of less than 70% of the lower plastic limit of the material did not decrease in density or gain materially in moisture content during the test.

Since no objection has been expressed relative to the 200-lb per sq in. load requirement proposed for road-beds, comments on this proposal will be omitted. It should be suggested, however, that the use of a sheeps-foot roller with a unit weight of not less than 200 lb per sq in. must be used for developing this strength. Furthermore, adequate compaction of earth demands that the unit weight of the roller must be increased with increasing plasticity. Moreover, the continued application of this unit weight to road-bed layers, until penetration ceases, would constitute an adequate test for compressive strength and uniformity of compaction.

The writer's reasons for suggesting a 2-ft thickness of special compaction for the uppermost part of the road-bed are as follows: (*a*) Road-beds in cuts are frequently composed of stratified, non-uniform or loose material which cannot be compacted adequately nor rendered water-tight without removal; (*b*) underground channels for water movement, if present, must be destroyed; (*c*) the uniformity of cut and fill sections of a road-bed should approach a constant density; (*d*) the cost of developing a given strength in a 2-ft thickness of road-bed by this method is commonly less than the cost of a 3-in. or 4-in. layer of granular material; and (*e*) road-bed compaction is a means of reducing the essential thickness of granular bases. A reduction in the thickness of this layer should be permitted only when this is warranted by the strength and water-tightness of underlying layers.

Mr. Campen and Mr. Turnbull have expressed doubt as to the necessity for restricting the pore space in the uppermost 2 ft of the road-bed to 70% of the lower plastic limit for the purpose of preventing critical softening. In reply to these objections, the writer would call attention to the authoritative definitions of the term "plasticity" recited by the writer under the heading "Solids." Moreover, the factor of safety suggested is only 70%, or as stated by Mr. Turnbull, 1.43. The writer had considered the advisability of suggesting the restriction of pore space to that of the lower plastic limit and depending upon entrapped air content to act as the sole factor of safety; but subsequent experience demands a more adequate factor of safety. Tests have frequently shown that pores sometimes become 100% saturated, although the values are commonly lower (Table 5, Column (18)). Since engineers usually recognize the need of various means for compensating for small variations in the uniformity of structural materials, it would seem that a value of 1.43 is not too great, especially since a factor of safety of 2 is in common use for structural steel, which is quite uniform in quality as compared to most clays.

The inability to compact poorly graded materials to certain densities, as pointed out by Mr. Turnbull, was implied although not adequately presented in the original paper. Obviously, size gradation is an essential to the production of strength and resistance to the penetration of water. A comprehensive method for the predetermination of ideal grading for maximum density of earth mixtures has been described by Charles H. Lee, M. Am. Soc. C. E., in 1938.[37] Although Mr. Lee's work is based upon the well-known experiments on aggregate for concrete by Sanford E. Thompson and the late William B. Fuller, Members, Am. Soc. C. E., in 1903,[38] supplemented by those of A. N. Talbot, Past-President and Hon. M. Am. Soc. C. E., and F. E. Richart, M. Am. Soc. C. E., in 1919 to 1923,[39] he shows the application of this law to earth mixtures. Mr. Lee has also developed a splendid form of graphical diagram based on Professor Talbot's equation and includes five cycles, ranging in size from 0.001 to 152.4 mm.[40]

Plasticity Index-Strength Relationship.—Mr. Campen makes the statement that the load-bearing value at any given water content varies with the plasticity index. In partial support of this statement, it may be safely stated that highly plastic clays, such as gumbos, commonly show high strength, but china and other clays of low plasticity are generally weak. The reader, however, should not infer that, because a certain clay shows a plasticity index of greater magnitude than that of a certain other clay, its cohesive strength is to be considered as being universally superior in resisting all types of forces. For the purpose of exemplifying any relationship of plasticity index to resistance of earth failure, Table 7 is shown. Cementation and absorption cylinders were 1 in. by 1 in. in size, molded under the usual pressures and dried under standard conditions.

[39] *Bulletin No. 137*, Eng. Experiment Station, Univ. of Illinois, October 15, 1923.

[40] *Proceedings*, Am. Soc. C. E., September, 1938, pp. 1438–1441.

The results of these tests indicate that, as a rule, the cylinders having low plasticity indices offered less resistance to blows and also to absorption of water than did those having high plasticity indices. However, it is also evident that the resistance to blows or slaking offered by the cylinders is not often indicated by the plasticity index.

Road-Bed Density and Pavement-Thickness Relationship.—Mr. Gray's contribution of design for "flexible type" pavements is sound in principle and his discussion is so practical and full of common sense that it should receive considerable attention. Moreover, his conclusions concerning the relationship between road-bed stability and pavement durability are quite apropos, regardless of the type of pavement laid.

In closing the discussion, the writer would stress the following essentials:

(*a*) Develop the road-bed material into the strongest and most water-resistant structure possible;

(*b*) Utilize selected local materials for enhancing the quality of the uppermost part of the road-bed; and,

(*c*) Complete the roadway with a pavement or wearing surface adequate for all requirements.

WATER-SOFTENING PLANT DESIGN

By W. H. Knox,[1] M. Am. Soc. C. E.

With Discussion by Messrs. Philip Burgess, A. Elliott Kimberly, L. R. Howson, Charles P. Hoover, M. H. Klegerman, Rollin F. MacDowell, D. E. Davis, and W. H. Knox.

Synopsis

In Ohio, the water supplies available in sufficient quantities to justify their development for municipalities are hard, almost without exception. The ground-waters used for municipal supplies range from about 60 ppm at a few supplies, derived from the sandstone region in the southeastern part of the State, to about 2 000 ppm in the northwestern part. The hardness of the surface water supplies does not vary through such a wide range. The average hardness of the Ohio River water throughout the year is about 100 ppm and the average hardness of the Lake Erie water is about 115 ppm. Most of the surface waters from streams within the State have an average hardness between 100 and 400 ppm; the maximum and minimum hardness of these surface waters fluctuates considerably above and below these averages.

Thus, it is seen that Ohio has been, and still is, a natural field for water softening. The first water-softening plant in the United States was installed in 1903 at Oberlin, and the first large plant in the United States was placed in operation at Columbus, in 1908. Very few plants were installed during the next fifteen years, there being a total of only six municipal water-softening plants installed in Ohio prior to 1924. Since 1924 the number of municipal water-softening plants has increased rapidly and, when plants now (April 1, 1938) under construction are completed, there will be 93 plants in the State. A total of approximately 4 800 000 population is supplied by the 450 municipal water-works systems in Ohio and 1 450 000 of these persons are supplied with softened water.

It is required by State statutes that the plans for water-works improvements (including water-treatment plants) shall be submitted to, and shall have received the approval of, the State Department of Health before construction of such works is undertaken. In reviewing the plans for such works since 1924,

---

Note.—This paper was presented at the meeting of the Sanitary Engineering Division, New York, N. Y., January 21, 1937, and published in May, 1938, *Proceedings*.

[1] Asst. Eng., State Dept. of Health, Columbus, Ohio.

the writer has had an excellent opportunity to observe the trend of the design of water-treatment plants in the State. This experience has been supplemented by visits to plants to observe the results being obtained and by the summaries of daily reports of operation that are submitted to the Department monthly. The size of the existing plants varies from the smallest plants, which have capacities of only 8 000 to 10 000 gal daily, to the Cincinnati Plant which has a rated capacity of 160 mgd. The plants in Ohio represent almost every type that can be constructed.

In this paper, an attempt has been made to avoid discussion of plant operation, the chemistry of the processes, and comments on patented equipment, except in so far as these items do affect the design of a plant.

Although the first water-softening plants were installed almost as early as the first rapid sand filtration plants, many more of the latter were built during the early years of the Twentieth Century. As a result, the design of the earlier water-softening plants was patterned somewhat after the design of water-filtration plants. The defects of such design and the need of special features for water softening were discovered by the operation of the plants and, hence, there has been a gradual change in design so that at present a softening plant is distinctly different from a filtration plant in which softening is not a part of the process. In this paper, only the special features of water-softening plants, which are not also features of filtration plants, will be emphasized.

SOURCE OF SUPPLY

If an existing well-water supply has a hardness of more than 700 to 800 ppm, another source of supply should be sought if a water-softening plant is to be installed. The cost of chemicals for water softening is, roughly, 1 cent per 1 000 gal for every 100 ppm the hardness is reduced. Hence, the cost of softening becomes burdensome when a very hard water is to be treated.

AERATION

For surface waters, aeration is sometimes an assistance in the removal of tastes and odors. For ground-waters it is advisable if considerable carbon dioxide or sulfur occurs in the water.

In recent years, patented aerators have been introduced as substitutes for the spray nozzles, coke trays, and step aerators. Limited tests have shown that such patented aerators require just as much head as, and are not any more efficient for aeration or removal of carbon dioxide than, non-patented devices. However, the patented devices are much more sightly, occupy less space, and cause less splash than non-patented devices. Therefore, consideration should be given to patented devices if their cost is reasonable.

Provisions should be made so that the aeration devices can be by-passed, the aerator devices cleaned, and the cleaning water drained to waste.

LIME-SODA WATER SOFTENING

The devices for handling chemicals—for adding chemicals to the water and for mixing them—are of major importance at a lime-soda softening plant.

These features should be considered first and the remainder of the plant built around these units.

Chemical Feed Devices.—Dry-feed machines have almost entirely superseded solution-feed devices for such plants except in small municipalities that have industrial or railroad types of softening plants, in which solution-feed devices are generally used.

In small plants it is desirable to provide an extra machine that can be used for more than one chemical; at larger plants, duplicate machines should be provided for each chemical. The machines should be placed as close as possible to the point of application so that the chemical solution can flow by gravity from the machines through short hose lines to the points of application. If this is not feasible, the chemical solutions should be conveyed in an open trough, or in hose lines supported continuously. If pipes are used to carry chemical solutions, such pipes should be accessible and should be provided with unions or other devices so that they can be removed and replaced quickly. Crosses at changes in direction to permit hose connections for flushing will assist in keeping the lines used for some chemicals clean; for lime, such flushing is useless.

Pneumatic equipment should be used for handling chemicals at large softening plants if the chemicals must be elevated. This is the most economical method of handling large quantities and permits the receipt of chemicals in bulk, which reduces the cost. For the plant of medium size a separate second-story room should be provided for the storage of chemicals in bags. Provisions should be made for elevating them to the storage room either by a hoist or by a bag conveyor. They can be dumped through openings in the floor of the storage room to the hoppers of the dry-feed machines. It is essential that connections to the hoppers be dust-proof.

For very small plants it is satisfactory to store chemicals in a room adjacent to the dry-feed machines and to carry the supply to the hoppers as needed.

Quick or Flash-Mixing Devices.—At extremely large plants it is desirable to obtain an intimate and thorough mixing of the chemicals with the water to insure that the water passing to all the subsequent treatment devices shall be of uniform quality. The hydraulic pump is used in a patented process as a flash mix at the Baldwin Water Purification Plant, at Cleveland, Ohio, and at the water-softening plant at Cincinnati. Various mechanical patented devices will also produce a flash mix. They have also been installed at some moderately large plants in Ohio. The writer questions the need of flash-mixing devices at medium or small plants, since a thorough mixing is obtained so quickly in the mechanical mixing devices at a water-softening plant.

Mixing Devices.—Baffled mixing chambers were used at the earlier plants. Mechanical mixing devices are preferable and have been installed at most of the plants constructed since 1924. Prolonged mixing is necessary to secure as complete reaction as possible and to avoid waste of chemicals. A detention period of 30 to 40 min is desirable and in no case should the detention period be less than 20 min.

A wide variety of stirring devices have given fairly satisfactory results. In many of the earlier plants, they consisted of horizontal or vertical paddles rotated through a vertical shaft by a motor on top of the mixing chamber. Recent trends are toward patented mixers. The devices should provide velocities between 1 and 1.5 ft per sec.

When the plant is large enough to justify the installation of two mixing chambers, it is desirable to have the two basins arranged so that they can be operated either in series or in parallel. It is necessary, of course, to have provisions for draining the chambers completely, preferably by gravity. Large-sized hose connections should be provided for flushing sludge from mixing chambers, clarifiers, and settling basins.

Clarifiers.—The quantities of sludge produced in water-softening plants are much greater than at plain purification plants. Unless provisions are made for frequent removal, the capacity of the settling basins is soon decreased materially by accumulated sludge, in which case storage capacity must be provided in the design. For this reason, and also due to the fact that, in many instances, small quantities of sludge can be disposed of more easily than accumulated quantities, the settling basins at most water-softening plants are equipped with devices for continuous or frequent removal of sludge.

The settling basins at a water-softening plant (and also at a filtration plant) should be true settling basins rather than coagulation basins; that is, the chemical reactions and coagulation should be practically completed before the water enters the settling basins. This item, together with the fact that the precipitate in lime softening is heavier and settles rapidly, permits much shorter detention periods for settling basins equipped with devices for sludge removal than the long detention periods formerly provided for coagulation basins at water-purification plants.

Either a rectangular basin with a longitudinal flow, or a circular basin with radial flow, gives satisfactory results. Square basins with transverse flow tend to short circuit and, as a result, no basins of this type have been installed recently.

Most engineers are guided, to some extent at least, by the typical layouts furnished by the manufacturers of the sludge-removal equipment which they propose to use. Competition among manufacturers can be obtained on bids for sludge-removal equipment for either rectangular or circular basins. There is one item that must not be overlooked in the design of a plant where clarifiers are used: In most clarifiers the effluent discharges over a weir, and this causes a practically constant water level in the clarifiers; in most coagulation basins the effluent is drawn off through submerged orifices, or over submerged weirs, which permits a considerable fluctuation of the water level in the basins. Such fluctuation is not provided when the clarifier effluent discharges over a weir. Hence, the only storage of water available for filtration is that in the carbonation chamber and in the filters themselves, above the level of the wash-water troughs. This storage is quite limited and may not be sufficient to provide the necessary "cushion" between the low-service and the high-service pumps. Lack of such storage may cause difficulties in operation unless automatic devices are installed to secure co-ordination of the various devices. This "cushion" or storage may be secured in clarifiers by causing the effluent to discharge through submerged ports which will permit the water elevations to fluctuate.

If clarifiers alone are used as settling basins, a detention period of 2 hr is generally sufficient to secure a satisfactory clarified effluent. Some of the chemical reactions are not entirely completed within this period; nor would they be in several times this detention period. This deficiency is partly taken care of by recarbonation of the water.

It is essential that provisions be made for completely draining the clarifiers, preferably by gravity, in order to secure access to the sludge-removal mechanism. In colder latitudes a cover or superstructure over the clarifier may be necessary to avoid ice troubles, especially if a surface water is to be treated.

Plain Settling Basins.—At small plants it may still be desirable for various reasons, to install settling basins without sludge-removal equipment. Such basins should be designed and operated in a manner similar to the coagulation basins of a purification plant. A detention period of 4 to 6 hr should be provided for such basins.

Efforts to withdraw sludge through a manifold system or series of small openings in the floor of such basins while the basins are filled with water have been unsuccessful at two Ohio plants; such withdrawal of sludge can be, and is being, accomplished at industrial types of water-softening plants when the depth of water is at least as great as the diameter of the tank. Since sludge from plain settling basins is generally disposed of by discharging it into streams during high flows, it is essential that the basin be set sufficiently above flood levels so that it can be completely drained into the stream during flood periods.

Sludge Disposal.—This is one of the chief difficulties of lime-soda water softening. The disposal of lime sludge into a stream does not constitute "pollution" such as that caused by the direct discharge of sewage, but it does cause unsightly deposits on the banks and bed of the stream. However, this is still the most common method of sludge disposal; it is satisfactory only when ample flows and velocities in the receiving stream are available. One Ohio plant is fortunate in having a near-by abandoned quarry into which sludge can be discharged. Another large plant discharges the sludge into up-ground lagoons surrounded by earth embankments. Other plants discharge the sludge alternately into two or more lagoons, allowing one lagoon to dry out while the other one is in use; at these plants some of the accumulated sludge is sold or is given away to farmers for use as "agricultural lime." The latter method is fairly satisfactory when the sludge produced can be absorbed by local demands. Limited experiments have been made on sludge drying by drum filters. Experiments are also being made of incinerating the sludge to convert it to calcium oxide so that it can be used again in the water-softening process.

In sewage treatment, due to the offensive nature of the sludge produced, the disposal problem had to be solved, and the engineers and equipment manufacturers worked on this problem until, at present (1938), satisfactory sludge disposal can be provided for any sewage plant. A satisfactory means of disposing of lime sludge must be found within the near future, or a lime-soda type of water-softening plant will often not even be considered for this reason alone.

Recarbonation of Water.—Lime softening produces a supersaturation of normal carbonates of calcium and magnesium in the water. In order to avoid delivering an incrusting water, it is necessary to convert the normal carbonates into bicarbonates, and this is accomplished by applying carbon dioxide to the lime-softened water.

Before passing to the filters, the effluent from the clarifiers or settling basins is passed through a chamber in which carbon dioxide is applied to the water. On account of the high solubility of carbon dioxide gas, especially in caustic water, only a brief detention period is required. For structural reasons such chambers are generally compartments adjacent to, and of the same depth as, the settling basins. Although the reactions are practically instantaneous, a detention period of 5 to 10 min, or even a longer period, is generally provided.

Carbon dioxide is applied through grids of perforated pipes usually laid on, or slightly above, the floor of the chamber. If the chamber is of excessive depth, the grids are supported about 10 ft below the water surface in order to avoid excessive pressures. One item, sometimes overlooked, is that the carbon dioxide pipe from the compressor should enter the chamber at an elevation above the water surface in order to avoid siphon action. If the inlet and outlet are at about the same elevation, a transverse baffle should be installed to prevent short circuiting of the water.

Various methods of generating carbon dioxide gas are used. At most of the larger plants operated almost continuously, a coke furnace is used to produce carbon dioxide. The heat generated is frequently used for heating water. At smaller plants, especially those not operated continuously, it is difficult to keep a small coke fire burning and some other fuels, such as oil or natural gas, are desirable. Flue gases from coal fires are likely to contain phenols unless the combustion is quite perfect; the designer should be cautious in deciding to use flue gas if the water is to be chlorinated. If coke is used as a fuel the flue gas must be passed through a scrubber and a dryer: if gas is used as a flue, the flue gas need only be passed through a cooling tank. It is very essential that the gas passing to the compressor is dry.

The devices should be sufficient to provide at least 300 lb of carbon dioxide per million gallons of water treated. The capacity of the compressor required varies with the percentage of carbon dioxide in the flue gas, the character of the water treated, and the degree to which recarbonation is to be carried. Careful investigation should be made of the type of compressor to be used.

The recarbonation equipment is one item in a plant for which duplicate units are not absolutely necessary. Since many lime-softening plants have operated for years without recarbonation devices, there is ordinarily no reason why they cannot be discontinued for a few hours or a few days without any unsatisfactory results.

Gravity Filters.—The design of filters for a lime-soda type of water-softening plant is practically the same as the filters of a purification plant. There are several features, however, that require special attention. Filter influent pipes, even where recarbonation is practiced, tend to incrust rapidly with normal carbonates. Such pipes should be designed over-size to permit longer periods between cleaning. They should also be designed with as few changes in direction as possible; flanged crosses instead of bends should be placed at changes in direction to permit rapid access for cleaning. Where small pipes must be used, they should be provided with flanges or unions so that the entire pipe can be removed for cleaning. Since the influent water is not corrosive, the filter influent pipes may be made of light-weight steel, which is much less expensive for larger sizes than cast-iron pipe. For a similar reason, steel wash-water troughs do not corrode at a lime-softening plant. Since the filter sand will begin to incrust as soon as the plant is in operation, it is obviously unnecessary to specify that the sand shall not be acid soluble as generally called for in the specifications for ordinary filtration plants.

The removal, regrading, and replacement of sand in filters, is an item that is not peculiar to a softening plant but one that has been neglected in the design of both filtration plants and softening plants. A few features included in the design would greatly facilitate handling of filtering material: Ordinarily, it can be conveyed by a water ejector; a high-pressure water line at least 2 in. in diameter should be available at each filter; a permanent pipe line in the pipe gallery should extend to a storage room for filtering materials; there should be provision for temporary rigid or flexible connections to this pipe line at each filter; a room should be provided in which a bin, sufficient in size to hold the filtering material for one filter, can be placed; and, the filtering material from a filter can then be ejected to a sand washer and gravel grader from which the sand and gravel would pass to the storage bins. In returning the filtering material to the filters, the operation is reversed. Provision of such equipment would result in improved operation of plants.

Pressure Filters.—Pressure filters should not be installed unless they cannot be avoided. The sand in such units becomes incrusted, is not frequently inspected, and it is practically impossible to spade it. As a result the water frequently passes through cracks in the filters instead of through the filter media. Since pressure filters are only intended as clarifying devices at lime-softening plants, there is no sanitary objection to their installation where the water to be softened is a well water of satisfactory sanitary quality; pressure filters must not be used where bacterial purification of the water is necessary. The type of plant feasible with pressure filters is frequently of considerably less cost than a plant of similar capacity with gravity filters, and this fact may occasionally justify the use of pressure units.

ZEOLITE WATER SOFTENING

Although zeolite softening units have been used for household and industrial installations for a considerable length of time, the adaptation of this process for municipal water softening is of comparatively recent date. The first municipal plant in Ohio was installed at Lowellville in 1927. Such a plant quite often consists almost entirely of assembled equipment furnished by the manufacturer. For this reason there is frequently very little actual designing to be done by the engineer. Sometimes, his chief duty may be only to determine whether zeolite treatment is the best and most economical process for the water to be treated, and to write specifications so that the plant will be adequate and so that competitive bids will be received.

A number of the earlier municipal zeolite plants were "sold" directly to municipal officials by representatives of equipment companies. In these cases no investigation was made by a disinterested engineer to determine whether the type of plant offered was best suited to local conditions. As a result, some zeolite plants have been installed in places where they are, to say the least, not the most suitable and, in some cases, the plants have been absolutely unsatisfactory. These installations have been, and still are, a detriment to the zeolite-softening field. Reputable manufacturers of zeolite and zeolite equipment now prefer and generally insist that the municipality installing the water-softening plant be represented by a competent engineer experienced in this work.

A zeolite plant has several distinct advantages over a plant of the lime-soda type. The chief merits of this type of plant are: (1) The absence of a sludge disposal problem; (2) lower first cost; (3) simplicity of operation; (4) expert supervision of plant is unnecessary; and (5) single pumping, directly from the well to the distributing system, can be practiced in many instances.

There are also disadvantages to zeolite softening which may be listed as follows: (1) Zeolite softening alone cannot be used where bacterial purification is required; (2) waters containing objectionable proportions of iron and manganese are not suitable for zeolite treatment unless these minerals are removed prior to zeolite softening; (3) some types of zeolite treatment require a large proportion of wash and rinse water; and (4) zeolite treatment alone provides no pH-correction.

Plant Capacity.—It is impossible to rate the daily softening capacity of a zeolite unit by its surface area or by the volume of zeolite in the unit. Its daily capacity depends, among other things, on the number of times the unit is regenerated during 24 hr. Therefore, the engineer must be careful to give proper weight to this factor when considering units of various manufacturers.

Iron Removal Prior to Zeolite Softening.—If the untreated well water has an iron content very much in excess of 0.5 ppm, it is essential to remove it before softening; and it can ordinarily be accomplished by aeration and filtration. Iron and manganese in solution can be removed by base exchange, by regenerating the zeolite with salt. This principle is used at several plants where at least three zeolite units are installed. In these cases, two (or more) units are operated as iron-removal and softening units, while one unit is over-run after its capacity for softening is exhausted. This single unit is thus only effecting iron removal; the mixed water from the three units is delivered to the distributing system in order to avoid serving a water of zero hardness. In this case the operation of the various units is staggered so that each unit in turn is over-run. The writer has observed one plant successfully operated in this manner. At this plant it requires expert operation to deliver a satisfactory water of uniform quality. At some small villages where this type of plant has been installed and where only ordinary operation is provided, the iron content and the hardness of the plant effluent often vary through wide ranges.

pH-*Control.*—Zeolite treatment has no effect whatever on the pH-value. Waters containing iron ordinarily contain large quantities of carbon dioxide. At some plants, where iron removal and water softening are effected by base exchange, the effluent is practically free from iron. However, there has been no change in the pH-value of the water, and the calcium or incrusting material has been removed; as a result, the water re-dissolves iron either from deposits in the mains or directly from the piping system with the result that the water delivered to the consumer may have a greater iron content than the water delivered directly from the wells.

Adjustment of the pH-value of the water will eliminate these troubles. Aeration of the water will release the carbon dioxide and raise the pH-value. The pH-value of the water can also be adjusted by introducing alkali to neutralize the carbon dioxide. In that case, there must be a constant check on the pH-value of the water delivered. Since the alkali feeders are generally pressure devices similar in principle to the "alum pots" of pressure filters, it is rather difficult to secure a uniform rate of feed. At small plants it is almost impossible to secure the degree of attention necessary to obtain control of the pH-value by alkali feed.

The foregoing operation experiences are cited to emphasize the precautions necessary in the selection of the type of plant to be installed. Zeolite softening has a wide and increasing field. It is important that it shall not be handicapped and discredited because the water is unsuitable or because it has not been properly prepared for zeolite treatment.

Selection of Type of Plant.—After having decided that a zeolite type of water-softening plant is to be installed, the designing engineer must then weigh the merits of the various types. Among the items to be decided are: (*a*) Gravity *versus* pressure units; (*b*) kind of zeolite to be used; and (*c*) up-flow *versus* down-flow units. Some of these questions are inter-related, and a decision on one question may establish the type of unit to be installed. Especially for small plants, it is advisable for the designer to give serious consideration to the installation of the standard pressure units of a reputable manufacturer rather than to install gravity units of his own design.

If pressure units are to be installed, the direction of flow is established by the manufacturer whose equipment is selected. At all except one of the gravity zeolite plants in Ohio the units are the up-flow type. At the one gravity plant, where green sand or natural zeolite is used (synthetic zeolite is used in the others), the units are of the down-flow type.

Gravity zeolite units have (to a lesser degree) the same advantages over pressure units that gravity filters have over pressure filters; namely, that the operation of, and conditions in, the units can be observed at all times. The design of gravity zeolite units has been patterned after the design of gravity, rapid-sand filters. In a down-flow unit the design may be practically identical with the design of a gravity filter. In an up-flow unit the direction of flow is reversed and, therefore, changes in design are necessary. Zeolite softening units are generally deeper than gravity filters. The gravel layers supporting the zeolite are similar to the gravel supporting the sand in a filter. In down-flow units (where green sand is used) the depth of zeolite does not generally exceed 3 ft. In up-flow units the loss of head through them is considerably less than in the down-flow units and the zeolite may be 4 ft to 6 ft deep, and occasionally of even greater depth; similar depths are used for down-flow synthetic zeolite units. Greater depths of zeolite permit economy in the quantity of water required for washing and rinsing. Frequently, considerations defining the vertical limits of the plant structures, such as the loss of head available and the lowest elevation at which natural drainage can be secured, determine the depth of the zeolite units.

The rate at which water is to be passed through a unit determines the area needed. In down-flow units the rate is generally from 2.5 to 4 gal per sq ft per min. In up-flow units the rate may be 4 to 6 gal per sq ft per min, or even somewhat higher.

In the design of the concrete up-flow softening units there are several significant items. The collecting or effluent troughs (corresponding to the wash-water troughs of a gravity filter) need to be designed only for the maximum rate of flow through the unit. During regeneration of a unit the brine and rinsing water pass downward. The design of the water-distributing system or the rinse water collecting system in the bottom of the unit requires special attention to insure that no brine remains after it is rinsed. A system of perforated laterals such as those used in gravity filters is not satisfactory because the brine is heavy; it would collect below such laterals during regeneration and would gradually pass out after the unit is again placed in service, thus causing a salty water to be delivered from the unit. In order to avoid this condition the strainer system should be designed as a system of laterals with perforations on top of the laterals in which strainers are placed. After the laterals and strainers are installed the entire strainer system should be covered with a layer of grout to an elevation just below the openings. Since the so-called re-wash valve is used every time a unit is regenerated, it should be as accessible as the others.

Proportioning Devices.—It is not satisfactory to deliver the water from the softening units directly to the distributing system since it is of practically zero hardness. Hence, some means must be provided to mix hard water with the effluent from the softening units in order that water of the desired degree of hardness may be delivered to the distributing system.

At a small plant this may be accomplished by installing a hard-water by-pass line on which a valve and a meter are placed. The hardness of the mixed water can be adjusted sufficiently by throttling the valve on the by-pass line. Zeolite equipment companies now furnish automatic proportioning devices to control the quantity of water by-passed; the installation of such devices is almost a necessity for larger plants and is desirable even for small plants.

If the raw water contains objectionable quantities of iron, and if zeolite treatment is provided to remove iron as well as for softening, the by-passed water may also have to be treated for iron removal, in order to prevent the mixed water from having an objectionable iron content. Since the hardness of a well water varies only slightly throughout the year, the proportioning devices need only to be changed infrequently after they are once set.

Salt and Brine Devices.—A considerable economy can be effected if salt is purchased in bulk instead of in bags. For this reason almost all plant administrators purchase salt in bulk. A desirable method of storing salt is to provide a basin into which it can be dumped from a truck or a railroad car. Such a basin should be provided with a tight cover, preferably of concrete. It should have a capacity sufficient to hold at least a month's supply, and should be kept filled with water. The salt rests on layers of sand and gravel over the floor which should drain to a gutter in which there are half tile or other brine-collecting devices.

At most plants, where there are gravity zeolite units, the concentrated brine passes from the salt-storage tank to a brine-measuring tank where the brine is diluted with water to the desired strength for regenerating the zeolite. The measuring tank is usually of a capacity sufficient to provide for the regeneration of one unit. If the brine cannot pass by gravity from the salt-storage tank to the brine-measuring tank, it is desirable to place the brine pump at such an elevation that there will always be a positive head on the suction of the pump. The concentrated brine may be ejected to a softening unit; in this case, the water from the ejector provides the dilution to reduce the brine to the desired strength for regeneration.

Back-Wash and Rinsing.—Down-flow units must be back-washed in the same manner as gravity filters, although generally at a lesser rate. If the hard water is clear and free from iron, it may be desirable to back-wash and to rinse the units with hard water instead of softened water. The designing engineer should secure accurate information regarding the percentage of water required for back-washing and rinsing. This feature is a factor that is often neglected in deciding the relative merits of lime-soda *versus* zeolite softening.

CONCLUSIONS

The public in Ohio is just becoming aware of the fact that softened water can be made available in almost any locality at a cost only slightly greater than the rates being charged for hard water. The field for water softening is practically unlimited. This offers water-works engineers an opportunity to serve the public; and it also offers an opportunity to design and install treatment plants for municipalities where previously it has been thought that water-supply and water-treatment problems had been definitely solved.

Since it is desirable to profit as much as possible by past experiences, the writer offers the comments in his paper in the hope that they may be of assistance to engineers engaged in this type of work. In accordance with Society policy, he has purposely refrained from comments on specific patented methods, processes, or equipment. It is suggested that discussers observe the same limitations.

DISCUSSION

Philip Burgess,[2] M. Am. Soc. C. E. (by letter).—To a striking degree, the valuable data contained in this paper should be very helpful to engineers who are concerned with the design of water-softening plants. It is to be regretted that more data could not have been presented which would substantiate some of the author's conclusions in a helpful manner.

Mr. Knox states that he is emphasizing only the special features of water-softening plants that are not features of filtration plants. However, his discussion contains valuable data with respect to many features that are included in both types of plants. It is not an uncommon experience for an engineer to be called upon to convert a rapid sand filtration plant into a water-softening plant. Such a problem includes generally the addition of more storage and of devices for the application of much larger quantities of chemicals, and the disposition of the resulting large quantities of sludge entailed by the softening process.

Furthermore, the author states that the pneumatic equipment is preferable for handling chemicals at large softening plants if the chemicals must be elevated. In general, pneumatic equipment is desirable because it eliminates the dust problem and permits ground storage of chemicals in bulk; at the same time it provides means for elevating the chemicals from ground storage to elevated tanks, or hoppers, through which the chemicals are fed by gravity as required. The writer would suggest also the use of automatic weighing machines as an adjunct to the dry-feeding equipment.

That feature of a water softening, as well as of a modern rapid sand filtration, plant which has been least appreciated, is the necessity for proper mixing of chemicals after their application with the raw water. Old plants frequently contained baffled mixing devices which, as the author states, are unsatisfactory because they do not permit the required flexibility of operation. Furthermore, it is difficult to secure proper distribution of the water as it leaves such tanks and enters the settling tanks. Modern devices of the flocculator type permit flexibility of operation and also proper distribution of the water to the settling tanks.

Reaction tanks should permit flexibility of operation at proper velocities, which the author states should be between 1 and 1.5 ft per sec. Experience indicates that slow velocities are not effective and higher velocities are harmful because they break up the coagulated floc.

The writer is interested in the design of two plants, each of 10 mgd capacity, wherein it is not now proposed to soften the water but which are to be designed so that softening may be added at minimum cost. This means that suitable devices are to be provided for storing and handling the larger quantities of chemicals and that the basins are built to allow sludge removal devices to be added when desired. No other changes are essential.

Rapid sand filters designed for filtering softened water should be equipped with devices which will permit washing at unusually high rates. This tends to decrease the deposition of after-deposits on the sand and is helpful in eliminating sand troubles and cost of maintenance. Furthermore, the filter sand may be comparatively coarse and inexpensive and need not be more than 24 in. deep. The filters are not required to improve the pathological quality of the water, but act rather in the nature of finishing devices wherein the coagulating reactions are completed, and some suspended matter is removed from the treated water. They seldom accomplish any substantial bacterial removal.

---

[2] (Burgess & Niple), Columbus, Ohio.

On the contrary, most of the solids in a softening plant are removed in the settling basins and it is of major importance that the engineer design these basins so as to permit proper displacement of the water with continuous flow through them. Inlet and outlet devices should be efficient and the basins should be properly designed with respect to depth, surface area, and velocity of flow. The author has not discussed these features of design, and it is hoped that he may add some data pertaining to them in his closing discussion.

The matter of providing covers for the basins and for the reaction tanks is of importance. It is noted that frequently engineers will cover the mixing tanks and will not cover the settling basins. In cold climates, the reverse is necessary because the settling basins must be covered to prevent trouble from ice which would not be experienced in the reaction tanks where the water is flowing at comparatively high velocity.

In designing re-carbonation devices, the engineer should appreciate that the gas supplied is of a toxic or poisonous nature and the features for handling it should be designed accordingly.

The author might have stated in his comments on the design of zeolite softeners that the wash water required in such plants may be 15% to 20% of the total quantity of water softened as compared with 3% to 4% of wash water generally required for the usual water purification plant. On the other hand, the disposal of sludge is the unsolved problem in connection with the operation of lime softeners and there is no such problem in connection with the zeolite plant.

The writer is not in accord with the author to the effect that zeolite plants should be designed by the manufacturer who is now in a position similar to that of the manufacturer of filtration-plant equipment some years ago. The engineer should inform himself so that he is capable of designing such plants and should not be dependent upon the manufacturer.

In conclusion, the writer believes that the author has rendered a distinct service to the profession in presenting much of the basic data required for the proper design of water-softening plants.

A. ELLIOTT KIMBERLY,[3] M. AM. SOC. C. E. (by letter).—Engineers interested in water-softening plant design will appreciate Mr. Knox's timely and informative review of current design practice. The author has had the unusual opportunity of examining plans for water-softening plants submitted during the twelve years, 1925–1937, to the Department of Health of a State in which ground and surface waters greatly exceed acceptable economic limits of hardness. This paper emphasizes the important, essential differences between water-softening and water-purification plant design, especially as regards the application of chemicals, the substitution of mechanical agitation for baffling, and the maintenance of continuously effective settling tank capacities through effective mechanical means for continuous sludge removal.

---

[3] Cons. San. Engr., Columbus, Ohio.

Experience has shown definitely that effective softening and the economic use of softening agents at lime-soda softening plants are dependent upon proper mixing at non-depositing velocities, generally obtained by the use of mechanical devices, assisted by a certain percentage of sludge return. Such a plan insures a maximum softening effect without waste of chemicals.

An important unsolved problem in lime-soda softening at municipal plants is the matter of sludge disposal. Doubtless, many engineers recall the difficulties which attend efforts to flush from a settling basin a compacted sludge containing from 13% to 15% of solids, the accumulation of many months, awaiting sufficient stream flow, and the serious problems which arise when no stream is available for dilution, or when no quarry-pits or other places of disposal are available. Due to the lime-sludge disposal problem, lime-soda softening is frequently rejected in favor of zeolites, even in cases where the former may be definitely more adaptable to raw-water conditions. The solution of this problem lies in lime recovery.

In 1915, Charles P. Hoover, Chemist-in-Charge of the Columbus Water Works, conducted extensive experiments at Columbus, Ohio, and actually operated the Columbus plant for a period of 4 hr with 5 000 lb of lime produced at a practical lime recovery plant. The softening results are stated as normal and satisfactory. The recovery plan was as follows:[4] The settling basin precipitate is pumped into a thickener from which the material is fed directly into a rotary kiln. The kiln used in these tests is 20 ft long and 34 in. in diameter and was oil fired. The sludge contained 18% of solids and from it was produced quick lime containing from 63% to 73% of water soluble calcium oxide.

A lime recovery plant, in successful operation in England, comprises duplicate agitated mixing tanks into which the sludge from the settling tanks is pumped.[5] The mixed sludge containing about 25% of solids is pumped to a vacuum filter, which reduces the water content to about 50 per cent. The filter is 8 ft in diameter by 8 ft wide and operates under a 16-in. to 20-in. vacuum. The filter cake discharges by gravity into a rotary kiln 86 ft long and 6 ft in diameter, operating at the rate of 1.33 rpm. From 12 to 14 hp are required to drive the kiln, which is oil-fired.

The capacity of the kiln is about 17 tons per day. The oil consumption is stated as 27% of the lime produced. The maximum temperature reached is about 1 500° C. Provisions are made for preventing dust by passing the evolved gases through a suitable dust collector. The results obtained at this plant are said to be highly satisfactory.

In the fall of 1935, studies were made by the Nichols-Herrshoff Company to determine the possibilities of incineration of lime-sludge reduced in volume by thickeners and vacuum filters, following the treatment successfully applied in the incineration of sewage sludge.

---

[4] Forty-fifth Annual Rept., Div. of Water, City of Columbus, Columbus, Ohio, 1915.

[5] *The Industrial Chemist*, July, 1933.

The need for a satisfactory practical method for the disposal of lime-sludge is evident. The successful application of filtration and incineration may solve the problem, obviously, to effect marked economies in water-softening plant operation. Many of the Ohio water supplies softened with lime and soda ash contain substantial quantities of magnesium (average 9% of the total hardness of Ohio ground-waters) and, consequently, sludge calcination results in the production of an admixture of calcium and magnesium oxides.

In a private communication with the writer, Mr. Hoover points out that, by a change in design which makes possible a two-way application of lime (additional mixing basins and clarifier units), it is possible to precipitate lime sludge containing practically no magnesium. This result is accomplished merely by holding the potential of hydrogen (pH) of the water at a point below that required to precipitate the magnesium. Since, ordinarily, considerably more reclaimed lime is produced at a plant than is required to soften the water, the two-way lime dosage plan suggested by Mr. Hoover should have definite application in practice, in cases where lime recovery is planned at softening plants treating water relatively high in magnesium salts.

Lime-soda softening was used in 1936 to effect a reduction of fluorides.[6] Briefly stated, it has been determined that, in the presence of magnesium salts, the application of lime to a water containing fluorides effects a fluoride reduction which, between the limits of 1.5 and 3.5 ppm, initial fluorides, varies as the square root of the magnesium removal. Clinical data indicate that fluorides on the order of about 1.0 ppm have no deleterious effect on teeth enamel. Mottled enamel is endemic in about twenty-eight States and, therefore, the advantages of lime treatment, with or without complete softening, appear definitely important.

Quite recently, a new type of zeolite has been developed which produces either carbonic, sulfuric, or hydrochloric acid, depending upon the composition of the raw water. Where carbonates predominate, a definite quantity of carbonic acid is produced. Using this zeolite, a certain percentage of the raw water is by-passed through a filter and, later, is admixed with the lime-softened water to adjust the potential of hydrogen. The process has the advantage that the quantity of carbon dioxide produced is constant and that no phenols or other objectionable materials are introduced into the water.

Prior to 1937, installations were limited to commercial practice, but in the latter part of May of that year a small unit went into operation at a softening and fluoride reduction plant at Mt. Victory, Ohio. The efficiency of this so-called "hydrogen zeolite" unit has been investigated by the Division of Engineering of the Ohio Department of Health. The results are said to justify the statement that the equipment is satisfactory.

Recarbonating with "hydrogen zeolite" is of much interest to the water-works designer since, with the use of zeolite, the quantity of carbonic acid is fixed so long as the composition of the well water remains unchanged, whereas using flue gases or burning gas or coke, the percentage of carbon dioxide produced is variable, thus preventing a close control of recarbonation.

---

[6] *Journal*, Am. Water Works Assoc., January, 1937, Vol. 29, pp. 9–25, inclusive.

L. R. Howson,[7] M. Am. Soc. C. E. (by letter).—The fact that approximately one-half the municipal water-softening plants of the United States are found in Ohio offers more than passing tribute to the contributions of the Ohio State Department of Health in acquainting the citizens of Ohio, not only with the necessity of securing a bacterially satisfactory water, but with the advantages to be secured from a reduction in the hardness as well. Without question, water softening in Ohio has paid large economic dividends.

The engineer who undertakes to design water filtration works is frequently aware of the ultimate, if not the present, desirability of softening, as well as filtering, the supply. When that is the case, the design should be made so as, economically and practicably, to install sludge removal equipment and other facilities necessary to the adaptation of the filtration plant to water softening. In the Milwaukee, Wis., plant (capacity 200 mgd), mixing design and periods follow softening practice. The settling basins are designed so that sludge-conveying equipment can be installed economically at a later date. It is believed that within the next decade, more or less, many plants treating Lake Michigan water with a hardness of 125 ppm will include softening.

With respect to aeration, it is the writer's belief that when used with surface waters for the removal of tastes and odors, some of the more positive and complete methods of control, such as activated carbon, are to be preferred. An experience has come to the writer's attention in which one of the inspirator type of aerators was installed for carbon dioxide removal before the lime treatment of a well supply. Red water troubles resulted, due to the presence of oxygen absorbed by the water. By-passing the inspirator type of aerator and using a simple splash type overcomes the red-water trouble in this plant.

In the moderate-sized softening plants chemicals, in general, are stored overhead. In the larger plants, elevated storage becomes costly and it is usually desirable to provide ground storage with only a limited overhead storage, transfers from ground to elevated storage being made at frequent intervals through dust-proof conveying equipment. Vacuum fan exhausters are frequently installed to remove dust from dry-feed machines during the charging operation.

Mr. Knox properly calls attention to the fact that mechanical mixing devices must be provided for water softening, and that the mixing period must be relatively long. Experience with stirring devices of both the horizontal-paddle, vertical-shaft type and the horizontal-shaft, flocculator type, leads to the opinion that the latter is much to be preferred. It has been found difficult to prevent the accumulation of sludge deposits where the vertical-shaft, horizontal-paddle type of equipment is used.

Where flocculators are used in softening, the peripheral velocity is ordinarily from 2 ft to 3 ft per sec, compared to from 1 ft to 1.5 ft per sec where alum is used for plain filtration.

Where softening is practiced in conjunction with the filtration of a sometimes turbid surface supply, provision for series operation is desirable. At times of high turbidity the first stage is used for the removal of turbidity with the second operated as single-stage softening treatment. Two-stage recarbonation is also being frequently adopted.

---

[7] Cons. Engr. (Alvord, Burdick & Howson), Chicago, Ill.

As Mr. Knox states, sludge disposal is one of the big unsolved problems in water softening and on that account is probably one of the greatest deterrents to the adoption of lime-soda softening in some cities. It has been found practicable at some localities, by continuous removal of the sludge in small quantities, to discharge it into the sewer system. Although the volume of sludge is considerable the effect of the lime in sweetening the sewage and the sewage sludge is beneficial providing the quantity of sludge is not out of proportion to the sewage into which it is discharged.

In the smaller and moderate-sized softening plants the building heating system quite frequently consists of oil-fired or gas-fired boilers. With oil, two boilers are commonly provided—one of sufficient capacity to provide all the carbon dioxide requirements, and the other of sufficient capacity to furnish all the heat required. There have been a few installations in which two burners have been installed under only one boiler, but the difficulty of securing good combustion and of controlling the carbon dioxide content of the gases under widely varying demands is difficult to overcome.

Filtration rates as high as 3 gal per min per sq ft are commonly used in softening plants treating well water. With proper pre-treatment the sand should not require replacement for many years.

Mr. Knox is to be congratulated on having condensed his broad observations on water softening into such a concise, yet comprehensive, discussion.

CHARLES P. HOOVER,[8] ESQ. (by letter).—The lime-soda ash water-softening plants that have been built in the past were not designed to produce softened water of any predetermined alkalinity or pH-value. This is probably due to the fact that, to this time, no definite values have been agreed upon for the calcium carbonate alkalinity and the pH-value of the softened water.

What should they be? Results of experimental work, conducted during 1935 and 1936 at the Columbus, Ohio, Water Softening and Purification Works, lead to the conclusion that if the softened water is to be in contact with galvanized plumbing, the potential of hydrogen should range from about 7.8 to 8.2, and the calcium carbonate alkalinity should be sufficient to produce saturation at these pH-values. In other words, the water should be in chemical balance to calcium carbonate. A pH-value of 7.8 to 8.2 means a water free from normal carbonates.

Low-alkalinity water containing all, or nearly all, normal carbonates (especially in hot water) is more corrosive to galvanized metal than water containing no normal carbonates. Results of recent experiments indicate that normal carbonates (calcium and magnesium) deposit an uneven scale, in hot water tanks from $\frac{1}{32}$ in. to $\frac{1}{16}$ in. thick, in a year's time which is only somewhat adherent; whereas, the bicarbonates of calcium and magnesium, although they produce a thinner scale, produce one that adheres much better to the metal. The bicarbonates, therefore, produce a much better protective coating on galvanized surfaces than the normal carbonates.

---

[8] Chemist in Chg., Water Softening and Purification Works, Columbus, Ohio.

When recarbonation of lime-softened water was first adopted and accepted as an essential part of water softening, about 1925, it was thought that its use would eliminate all filter-sand troubles, and all incrustation and corrosion problems in the distribution system.

Water-softening treatment, it is believed, can be made to eliminate distribution troubles, but thus far no practical means has been found to eliminate incrustation of filter sand entirely and, at the same time, produce the desired alkalinity. Tentative results from incomplete experiments indicate that the following procedure seems promising as a means for removing or crystallizing colloidal precipitates, and thus prevents them from crystallizing on, and coating, the sand grains:

(*a*) The addition of precipitated calcium carbonate, water-softening sludge, or other finely divided inert substances to the softened carbonated water, then stirring and settling before filtration;

(*b*) Blanket filtration of the softened carbonated water through precipitated calcium carbonate, water-softening sludge, or other finely divided inert material; and,

(*c*) If water is carbonated and then allowed to settle for a long period of time before being filtered, sand troubles will be eliminated, but the settling time must be measured in hours and days rather than in minutes.

The difficulty is that precipitates resulting from water-softening reactions are least soluble at a high pH-value (about 9.4) and if enough carbon dioxide is added to bring the potential hydrogen below this value more of the precipitate stays in solution, and colloidal precipitates are dissolved. The alkalinity or the carbonate hardness is thus increased beyond that desired. Therefore, the addition of carbon dioxide to softened settled water just ahead of the filters in sufficient quantity to stabilize it (so as to prevent incrustation and cementing together of the sand grains) cannot be practiced if it is desired to produce water of low alkalinity. This means that until a satisfactory procedure for removing colloidal precipitates is developed, sand filters will have to be resanded every ten or twelve years. Proper adjustment of the pH-value by the addition of carbon dioxide to lime-softened water should be made following filtration.

A careful study of Mr. Knox's paper by engineers who design water-softening plants should prevent them from repeating mistakes that have been made in the past. There are many items that might profitably be discussed; at least four of them should not be ignored:

(1) If a plant is designed to soften surface water that becomes extremely muddy during flood times, provisions should be made to coagulate and remove the bulk of the mud before the softening chemicals are added. The flow line would be to: (*a*) Add coagulant; (*b*) mix; (*c*) settle; (*d*) add softening re-agents; (*e*) mix; (*f*) settle; (*g*) carbonate; (*h*) filter; and, (*i*) adjust pH.

(2) Too much emphasis cannot be registered against the use of pressure filters for filtering lime-softened water. At a water-softening plant, it is

necessary to spade and break up the sand in the filter beds frequently, and it is almost impossible to do this where pressure filters are used.

(3) The importance of accurate chemical feeding devices decreases in almost direct proportion to the size of the plant; that is, the smaller the plant, the more necessity there is for accurate control. Automatic controls are especially desirable in small plants. Devices for weighing the softening reagents are preferable to measuring devices. The necessity for making provisions that will prevent arching of chemicals in hoppers is also very important.

(4) During the summer, there will be sweating from pipes and exposed concrete in plants treating cold well water. The difficulties from this source can be minimized by providing proper insulation and drainage; and it is especially important that the elevation of the filters be low enough that the level of the water in them may be kept below the elevation of the operating floor.

M. H. KLEGERMAN,[9] ASSOC. M. AM. SOC. C. E. (by letter).—Preliminary testing for the purpose of providing basic design factors is probably more readily possible in the field of water supply conditioning than in many other fields of engineering design. Such preliminary testing, or pilot-plant installations, may provide facilities varying from a simple laboratory jar-mixing set, to a model plant handling a substantial volume of water and equipped with diverse mechanical aids entering into the different steps in the treatment. The desirability of such procedure should be emphasized, if only but to confirm, in any particular instance, the suitability of accepted design factors for treatment of the water supply in question.

In a recent investigation for the treatment of the water supply of a Southern municipality, involving "excess lime" followed by recarbonation, a small pilot plant was installed which provided principally for: (*a*) Automatic chemical feed; (*b*) mechanical mixing with means for varying mixing speed and time of mixing; (*c*) "stage mixing" (that is, varying the speed of mixing from "fast" to "slow" as the flow proceeded from inlet to outlet of the mixing compartments); (*d*) settling, with provisions for varying the detention period; and (*e*) sand filters.

Without entering into a detailed discussion of the various factors derived from this investigation (which were principally of value to the particular water supply under consideration) it is of interest to illustrate at least one of the items noted which has application to the paper. That item pertains to the question of speed and time of mixing and time required for settling. The author has stated that where mechanical devices are used (see heading, "Lime-Soda Water Softening: Mixing Devices"), a 30-min to 40-min mixing time is desirable and that velocities provided by mixing devices should be between 1 and 1.5 ft per sec. As for the settling period, he states that a detention of 2 hr is generally sufficient to secure a satisfactory clarified effluent (see heading, "Lime-Soda Water Softening: Clarifiers").

---

[9] Associate, Alexander Potter, New York, N. Y.

Although these factors are generally confirmed by the tests conducted by the writer, these tests, nevertheless, indicated that mixing speed, mixing time, and settling time, were not independent elements, but bore a relationship; that is, various combinations of these three elements were capable of producing equivalent results.

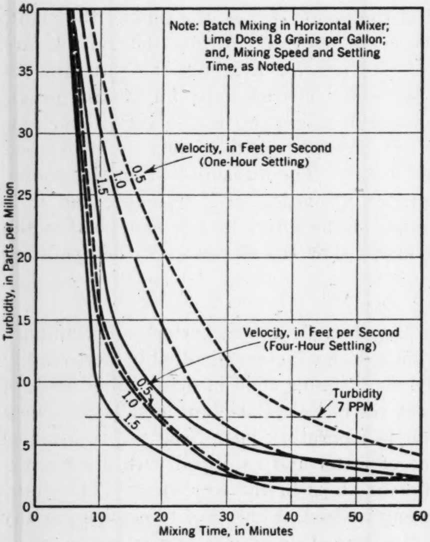

FIG. 1.—RELATION BETWEEN MIXING SPEED, MIXING TIME, AND SETTLING TIME

In illustrating this relationship, the writer will follow the policy adopted by the author of avoiding discussion of the chemistry of the process, and will use "turbidity" which is an index of the clarity of the settling-tank effluent as a basis of comparison. (The water supply in these tests emanated from limestone springs; it was clear and colorless so that any turbidity present in the settled water resulted only from the reacting chemicals.)

Fig. 1 indicates the average results of a series of "batch" tests, made in a rectangular mixing tank provided with power-driven mixing paddles mounted on a horizontal shaft, mixing being at right angles to the direction of flow. Means were provided for mixing at three different speeds. (The speed of mixing refers to the paddle-tip speed.)

The test procedure involved filling the mixing tank, introducing the previously determined lime dose (the same for each test), then operating the mixing device at a speed of 0.5 ft per sec for one series of tests, 1.0 ft per sec for another, and 1.5 ft per sec for a third. Samples were dipped from the mixing tank at intervals of 10 min for each test series, thus providing samples representing 10-min mixing at a given speed, 20 min, 30-min, etc. Two samples were taken at each interval, one being permitted to settle in a jar for 1 hr and the duplicate sample for 4 hr.

As will be noted from the curves, the same "end-point" as determined by turbidity measurements was obtainable with a number of variations. For example, assuming that the desired turbidity of the clarified effluent is, say, 7 ppm, the combinations in Table 1, in so far as this water supply is concerned, were found possible. These data indicate that, in general, for the same speed of mixing, cutting the mixing time in half requires quadrupling the detention time in the settling basins for equivalent clarity of effluent (compare Series *a* and *d* and Series *c* and *f*). It will also be noted that substantial reduction in time of mixing is possible at increased mixing speeds.

For example, the same result is obtained with 24-min mixing, at a speed of 1.5 ft per sec and 1 hr settling, as is obtained with equivalent mixing time (that is, 20 min) with only a speed of 0.5 ft per sec but with 4-hr settling (compare Series *c* and *d*). The cost of structures would be far greater in the latter case (Series *d*) than in the former (Series *c*). Similarly, sludge removal equipment would be more costly in the tanks providing for longer detention. Mixing equipment costs would be about the same, except that the drive units for the faster speed of mixing (Series *c*) would have to be powered substantially higher than that of the lower speed (Series *d*). Likewise, power consumption in the faster mix would obviously be much greater than that in the slower, the power requirements varying as the cube of the mixing speed. Thus, selection of final factors involves economic consideration.

TABLE 1.—Combinations of Mixing Speed, Mixing Time, and Settling Time to Produce a Tank Effluent of Identical Turbidity

(For This Illustration, Seven Parts per Million Was Selected as the Turbidity)

Speed of mixing, in feet per second	(*a*) Settling Time, 1 Hour		(*b*) Settling Time, 4 Hours	
	Series	Time of mixing, in minutes	Series	Time of mixing, in minutes
0.5.........	*a*	42	*d*	20
1.0.........	*b*	28	*e*	19
1.5.........	*c*	24	*f*	13

It is the writer's opinion that most conditions involving mixing of chemicals with water for coagulation warrant the provision of variable speed devices, particularly in view of the changing characteristics of the water in many instances, requiring, in turn, varying dosages of lime, soda ash, etc., for softening. The ease with which most mechanical mixers may so be equipped merits their adoption over baffling and hydraulic methods not readily controllable.

The author has given the profession a valuable "bird's-eye view" of standard practice in the field of water-softening plant design. It would be of additional value if data could be presented relative to filter-washing practice in which lime or lime and soda ash are the treating chemicals. Does incrustation of filter sand with lime warrant differences in filter-washing provisions not required in ordinary rapid sand-filter practice?

Rollin F. MacDowell,[10] M. Am. Soc. C. E. (by letter).—Very concisely, Mr. Knox has covered the main considerations in the selection of the type and the design of municipal water-softening plants. The writer offers a few additional suggestions from his experience in this field.

Municipal water softening is a relatively new field in public service, but has already proved to be practical and economically sound. It is no longer considered sufficient to provide only a clean water, free from pathogenic bacteria, and thus the number of water-softening plants constructed is accelerating rapidly. As of January 1, 1938, there were 362 municipal plants installed, or under construction, in the United States, of which Ohio had 90, or approximately 25 per cent.

---

[10] Cons. San. Engr., Cleveland, Ohio.

Mr. Knox states (see "Sources of Supply") that, if the hardness is more than 700 to 800 ppm, another source of water supply should be sought. Although this is true from a standpoint of cost, it does not mean that it is impractical to soften water containing 800 ppm, or more, of hardness. It is sometimes impossible to find another and softer source of supply. At Elmore, Ohio, the hardness of the raw water is about 1 060 ppm. This supply is softened to 70 ppm without difficulty and a satisfactory, palatable water is produced. The cost has not proved to be a burden. In fact, it was not necessary to raise the water rates in order to finance the cost of operation.

Aerators.—The writer agrees that it is not necessary to provide patented aerators in order to secure satisfactory results. Furthermore, non-patented aerators can be designed so as to be sightly. The patented aerators are usually entirely or partly of metal construction, which corrodes rapidly under the operating conditions that are usually most favorable to oxidation, thus causing the metal to corrode. Coke aerators can be made of concrete and cypress wood construction which is more permanent and requires less maintenance. Incidentally, if aerators are provided following softening, aluminum should not be used in the construction as the soft water pits this metal badly.

It is certainly true that sludge disposal "is one of the chief difficulties" of lime-soda water softening. This is especially the case in those municipalities, usually small, which are not on or near a sizeable stream into which the sludge can be discharged without sight nuisance. In such cases, and because of the sludge problem alone, the zeolite method of softening is usually advisable.

Type of Plant.—For every proposed plant careful consideration should be given by the designing engineer to all the factors involved in the determination of the type of plant to be provided. There are some factors, such as the sludge problem with lime-soda plants, which may make zeolite advisable aside from other considerations. On the other hand, if the raw water is from a surface source, or otherwise subject to pollution, or if the raw water has an objectionable fluoride content, the lime-soda method must be utilized; but, usually, the problem is largely an economic one, including first cost as well as cost of operation.

With the small plants having capacities as great as, say, 0.5 mgd, the saving in labor and the cost of technical control in the operation of zeolite plants quite often make this method advisable. This is especially true if automatic regeneration can be provided, thus eliminating the necessity for regular and frequent attention to the plant.

Troughs and Piping.—In gravity zeolite plants, because of the highly corrosive character of the salt brine used for regeneration, special attention should be given to the materials used for troughs and piping. For this reason, steel troughs are unsatisfactory, but concrete and asbestos cement have been used with success. For the collector and brine distribution systems, cast-iron pipe or material containing chromium and nickel is satisfactory.

Control Equipment.—With both gravity and pressure zeolite plants certain control equipment is found desirable. Automatic proportioning of the by-passed hard water is worth while, especially if the hardness of the raw water varies or two sources of raw water, having different degrees of hardness, are used.

With pressure zeolite plants in which the water is pumped from the source of supply or from a collecting basin directly through the pressure softeners, or through pressure filters and softeners, to the distribution system and elevated storage, provisions should be made to eliminate the surge in the pipe lines due to rapid starting of the pumps. For this purpose a slow opening discharge gate-valve, of the hydraulic type, operated electrically through the pump starter, is found to be effective.

Salt Storage.—The most economical method of purchasing and handling salt for regeneration is in bulk carload lots. A minimum carload is 40 tons. The wet salt storage basin, therefore, should have a capacity of at least 40 tons of dry salt, with ample free-board for float-valve control of the feed-water. Preferably, however, the basin should be divided into two compartments, each of which holds 40 tons of salt, in order that one compartment may be filled at any convenient time while the other is in service.

Brine pumps, which are usually of the centrifugal type, should be entirely brass-lined and mounted. If they cannot be located conveniently as to elevation to provide a positive head on the suction side, satisfactory self-priming units can be secured.

D. E. DAVIS,[11] M. AM. SOC. C. E. (by letter).—This paper will repay the careful study of those contemplating the construction of a softening plant. It brings into sharp focus a long first-hand experience of the essential design features that should be incorporated if success is to be attained. Communities have been slow to recognize that softening plants are a good investment; but at chemical costs of 1 cent per 1 000 gal per 100 ppm of hardness removed, as quoted by the author, combined with reasonable fixed charges, it is usually found that soap savings alone more than justify the expenditure for a plant.

With good reason, the author stresses the desirability of short, direct lines for conveying chemicals to the mixers, with adequate provisions for cleaning, since lime in particular tends to build up a dense coating. No plant feature is more important than the mixing chamber, preferably of the mechanical type in which the raw water and the chemicals are brought into intimate contact at a speed of rotation less than that which will break the floc, but fast enough to permit the building up of a large aggregate which will quickly settle in the clarifiers. The flow of water may well be in an upward direction, thus maintaining the floc longer in suspension while it is being built.

Perforated baffles at the entrance and exit contribute to even flow through settling basins, and provide the "fly-wheel" or "cushion" of storage for meeting fluctuations in softener rates, the advisability of which is stressed by the author. The combination of a clarifier followed by a settling basin should give better and more flexible operation than a clarifier alone.

---

[11] Engr. (The Chester Engrs.), Pittsburgh, Pa.

The disposal of the sludge, as the author shows, is one of the distinct limitations to the use of the lime-soda softening process under certain conditions, and more positive methods of meeting this situation may well be one of the design features in future plants.

Coke used for generating carbon dioxide for recarbonation should be low in sulfur content in order to prevent corrosion in compressors and lines. The author's suggestions relative to the design of piping which conveys water with a normal carbonate content is well taken, since it will usually be necessary to clean the deposit from these lines at intervals of several years.

The most careful study of the hydraulics of a zeolite plant is essential if head losses and sand rise are to be properly handled. The relationships between varying hardness, sand volumes, storage capacities, and wash and rinse waters require most careful study if the design is to prove successful.

In listing the disadvantages of zeolite, the author states that "objectionable proportions of iron and manganese are not suitable for zeolite treatment unless these minerals are removed prior to softening." This scarcely holds true for manganese in quantities as great as 7.0 ppm, and averaging 5.0 ppm for several years, because zeolite has been shown capable of removing these quantities continuously by base exchange and without damaging the green sand. However, manganese is not removed beyond the end of the period of zero hard water, but appears immediately with the first sign of exhaustion of the zeolite.

Professor W. F. Langlier has shown that changes in the calcium content of a water may have a material effect on its corrosive qualities.[12] Since in zeolite softening, calcium is removed or reduced, the resulting soft water is likely to be corrosive. This is sometimes offset by an increase in pH which accompanies the action of some zeolites.

When dealing with a pure, clean, but hard water, a zeolite plant offers many advantages, including low first cost and "fool-proofness" in operation. The choice of type of softening plant for a given situation can only be determined after a careful examination and weighing of the various determining factors.

W. H. Knox,[13] M. Am. Soc. C. E. (by letter).—The seven discussions do not disagree with, or contradict, the writer's statements. Mainly, they amplify various items mentioned briefly in the paper, and thus give valuable additional information.

In an article of restricted length on such a broad subject only the salient features could be included. A textbook would have to be written to discuss details of all features of a water softening plant. Hence discussions could be continued indefinitely, since the design of such plants is changing continuously. Considerable time has elapsed since the paper was prepared and some minor items would be changed due to progress in the art.

The number of water softening plants is rapidly increasing, especially in the Middle West. If the present paper has helped in the understanding of the problems involved it will have served a useful purpose.

AERODYNAMICS OF THE PERISPHERE AND TRYLON AT WORLD'S FAIR

BY ALEXANDER KLEMIN,[1] ESQ., EVERETT B. SCHAEFER,[2] ESQ., AND J. G. BEERER, JR.,[3] ESQ.

WITH DISCUSSION BY MESSRS. ELLIOTT G. REID, KARL ARNSTEIN, AND W. B. KLEMPERER.

SYNOPSIS

There can be no better way of beginning this paper than to quote the following recommendation from the pamphlet, entitled "Standards of Design for Structural Steel," (1)[4] published by the United States Navy Department:

> "For structures of unusual character or magnitude where the wind is an important factor, the actual distribution and intensity of positive and negative wind pressure should be investigated, preferably by wind tunnel tests of a scale model, and the stresses calculated on that basis should be used if they exceed those determined from the formula given herein."

Certainly the Perisphere and the Trylon, the "theme" buildings at the New York World's Fair, come under the designation of structures of unusual character and magnitude—since the Perisphere is a hollow spherical building with a diameter of 200 ft, and the Trylon is a tapered triangular prism-like object, 675 ft high. The group, with a variety of supports for the sphere collars and columns, is shown in Fig. 1. The difficulty in estimating the wind loads, and especially their distribution, on these two buildings was all the greater since they are in close proximity to one another. Because of mutual interference they must be considered as a single aerodynamic unit, since no prior experimentation was available as to the aerodynamic effects on a sphere close to the ground, and since, in general, the contemplated project is without parallel in structural history.

Accordingly, the senior writer immediately suggested the advisability of a systematic wind-tunnel investigation. The paper is an account of these experiments, accompanied by theoretical considerations.

NOTE.—Published in May, 1938, *Proceedings*.

[1] Chairman of Dept. and Prof. of Aeronautical Eng., Daniel Guggenheim School of Aeronautics, Coll. of Eng., New York Univ., New York, N. Y.

[2] Instructor in Aeronautical Eng., New York Univ., New York, N. Y.

[3] Graduate Student, New York Univ., New York, N. Y.

[4] Numerals in parentheses, thus (1), refer to items in the Appendix, List of References.

The experimental results constitute an addition to the meager information available on the aerodynamics of buildings, and may find application in the design of other structures, such as circular gas tanks, triangular towers, etc. In general, the technique of the investigation should be of interest to structural designers who have to deal with wind loads.

From a theoretical point of view the main interest of the paper lies in the mathematical study of the air flow around a sphere when in proximity with the ground, and the comparison of the calculated results with those obtained experimentally.

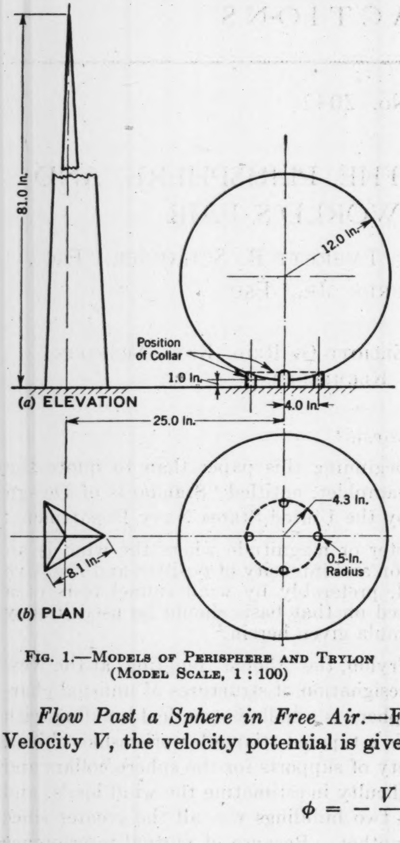

FIG. 1.—MODELS OF PERISPHERE AND TRYLON (MODEL SCALE, 1 : 100)

THEORETICAL CONSIDERATIONS

In examining the results of the tests of pressure distribution over the Perisphere, a useful check is provided by theoretical calculations of the potential flow past a sphere in free air, and of the potential flow past a sphere close to the ground. There is also scientific interest in comparing the actual flow with the potential flow.

Flow Past a Sphere in Free Air.—For a sphere moving in free air with Velocity V, the velocity potential is given by,

$$\phi = -\frac{V a^3 \cos \theta}{2 r^2} \dots\dots\dots\dots\dots\dots (1)$$

in which, a = radius of the sphere; r = distance from the origin to any point; and θ = angle between Vector r (Fig. 2) and the direction of motion of the sphere. If the sphere is at rest, and the air is flowing past it with Velocity V, the velocity potential becomes,

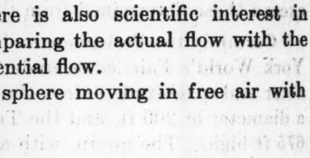

FIG. 2

$$\phi = -\frac{V a^3 \cos \theta}{2 r^2} - V r \cos \theta \dots\dots\dots\dots\dots\dots (2)$$

The velocity at right angles to Vector r is, therefore,

$$V_n = \frac{\partial \phi}{r\,\partial \theta} = \left[\frac{V\,a^3}{2\,r^3} + V\,r\right] \sin\theta \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

and over the surface of the sphere, the tangential velocity over any great circle whose diameter is along the direction of the general flow is,

$$V_t = \frac{3}{2}\,V \sin\theta \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (4)$$

with a maximum velocity of $\frac{3}{2}\,V$; in which, $\theta = 90$ degrees.

If p_∞ is the static pressure at infinity, where the flow is undisturbed by the presence of the sphere, and p_n is the normal pressure at any point on the sphere, then by Bernoulli's equation,

$$p_\infty + \rho\,\frac{V^2}{2} = p_n + \frac{V_n^{\,2}}{2} \ldots (5)$$

and,

$$p_n - p_\infty = \rho\,\frac{V^2}{2} - \rho\,\frac{V_n^{\,2}}{2}$$

$$= \rho\,\frac{V^2}{2}\left[1 - \left(\frac{3}{2}\sin\theta\right)^2\right] \ldots (6)$$

Two Spheres of Equal Diameter Moving with Equal Velocity Along Parallel Lines.—In this case (see Fig. 3) it is clear that there will be no flow across the horizontal plane whose trace is the axis, $O\,X$. Therefore, the flow will be the same as if Sphere A or Sphere B were moving with the same velocity, V, in the presence of the boundary or ground, $O\,X$. To find the velocity potential in this case is the best introduction, therefore, to the problem of the flow past a sphere in the presence of the ground. In finding this velocity potential, an approximate treatment must be adopted because of the mathematical difficulties involved.

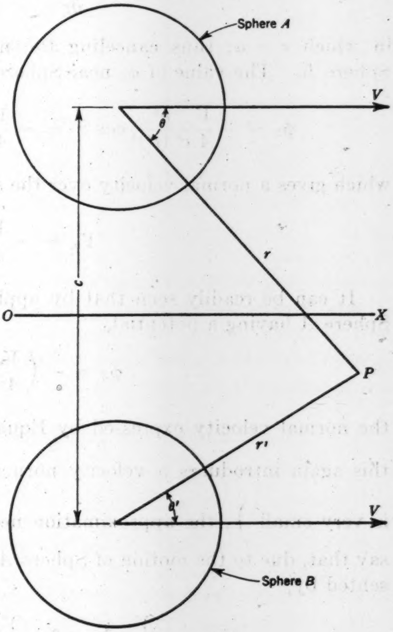

FIG. 3

Thus, if the velocity potential, ϕ_1, for Sphere A, moving with Velocity V, is expressed by Equation (1), then near Sphere B (see Fig. 2):

$$\phi_1 = -\,\frac{V}{2}\,\frac{a^3\,r\cos\theta}{r^3} = -\,\frac{V}{2}\,a^3\,\frac{r'\cos\theta'}{r^3} = \frac{V}{2}\,\frac{a^3\,r'\cos\theta'}{c^3} \ldots\ldots\ldots (7)$$

since $r \cos \theta = r' \cos \theta'$. The normal velocity over Sphere B is,

$$V_n = \frac{\partial \phi'}{\partial r'} = -\frac{V}{2}\frac{a^3 \cos \theta'}{c^3} \ldots\ldots\ldots\ldots\ldots\ldots (8)$$

that is, into Sphere B. Since there can be no velocity normal to a solid body, a space doublet is applied at the center of Sphere B having a velocity potential,

$$-\left[\frac{V}{2}\frac{a^3}{c^3}\right]\frac{a^3}{2(r')^2}\cos \theta' = \phi_2 \ldots\ldots\ldots\ldots\ldots\ldots (9)$$

which induces a velocity,

$$\frac{-\partial\left(\dfrac{V}{2}\dfrac{a^3}{c^3}\dfrac{a^3}{2\,(r')^2}\cos \theta'\right)}{\partial r} = \frac{V}{2}\frac{a^3 \cos \theta'}{c^3} \ldots\ldots\ldots\ldots (10)$$

in which $r = a$; thus canceling the normal velocity across the surface of Sphere B. The value of ϕ_2 near Sphere A is (approximately):

$$\phi_2 = -\frac{V}{4}\frac{a^6}{c^3\,(r')^2}\cos \theta' = -\frac{V}{4}\frac{a^6\, r' \cos \theta'}{c^3 (r')^3} = -\frac{V}{4}\frac{a^6\, r \cos \theta}{c^6} \ldots\ldots (11)$$

which gives a normal velocity over the surface of Sphere A equal to,

$$V_n = -\frac{V}{4}\frac{a^6 \cos \theta}{c^6} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$

It can be readily seen that by applying a space doublet at the center of Sphere A having a potential,

$$\phi_3 = -\left(\frac{V}{4}\frac{a^6}{c^6}\right)\frac{a^3}{r^2}\cos \theta \ldots\ldots\ldots\ldots\ldots\ldots\ldots (13)$$

the normal velocity expressed by Equation (12) will be canceled. Although this again introduces a velocity normal to Sphere B $\left(\text{since } c > a; \text{ and } \frac{a^6}{c^6} \text{ is very small}\right)$, the approximation need be carried no further, and one can say that, due to the motion of Sphere A, the velocity potential near it is represented by,

$$\phi_4 = -\frac{V}{2\,r^2}a^3 \cos \theta - \frac{V}{4}\frac{a^6\, r \cos \theta}{c^6} - \frac{V}{8}\frac{a^6}{c^6}\frac{a^3}{r^2}\cos \theta \ldots\ldots (14)$$

and also that, due to the motion of Sphere A, the velocity potential near Sphere B may be represented with sufficient approximation by,

$$\phi_5 = -\frac{V}{2}\frac{a^3\, r' \cos \theta'}{c^3} - \frac{V}{4}\frac{a^6}{c^3\, 2\,(r')^2}\cos \theta' \ldots\ldots\ldots\ldots (15)$$

Hence, the velocity potential near Sphere A due to the combined motion of both spheres must be, by considerations of symmetry,

$$\phi_8 = -\frac{V}{2\,r^2}\,a^3\cos\theta - \frac{V}{4}\,\frac{a^6\,r\cos\theta}{c^6} - \frac{V}{8}\,\frac{a^6\,a^3}{c^6\,r^2}\cos\theta - \frac{V}{2}\,\frac{a^3\,r\cos\theta}{c^3} - \frac{V}{4}\,\frac{a^6}{c^3}\,\frac{\cos\theta}{r^2} \tag{16}$$

Air Flow Past a Sphere in Presence of the Ground.—To bring the air into motion and the spheres to rest, it is now only necessary to add the term $-Vr\cos\theta$ to Equation (16) and the complete expression for ϕ_7 is the result. When $r = a$,

$$\phi_7 = -\frac{V}{2}\,a\cos\theta - \frac{V}{4}\,\frac{a^6}{c^6}\,a\cos\theta - \frac{V}{8}\,\frac{a^7}{c^6}\cos\theta - \frac{V}{2}\,\frac{a^4\cos\theta}{c^3} - \frac{V}{4}\,\frac{a^4}{c^3}\cos\theta - V\,a\cos\theta \tag{17}$$

and the tangential velocity is:

$$\begin{aligned}\frac{\partial\phi}{a\,\partial\theta} &= V\sin\theta\left[\frac{1}{2} + \frac{1}{4}\,\frac{a^6}{c^6} + \frac{1}{8}\,\frac{a^6}{c^6} + \frac{1}{2}\,\frac{a^3}{c^3} + \frac{1}{4}\,\frac{a^3}{c^3} + 1\right]\\ &= \frac{3}{2}\,V\sin\theta\left[1 + \frac{1}{2}\,\frac{a^3}{c^3} + \frac{1}{4}\,\frac{a^6}{c^6}\right]\end{aligned} \tag{18}$$

For maximum velocity $\theta = 90°$ in Equation (18), and $\sin\theta = 1$. It is seen that the tangential velocity is greater for the sphere in the presence of the ground, than for the sphere in free air. Another interesting phenomenon is that the velocity, theoretically, is dependent only on the value of θ, and is the same at symmetrical points above and below the sphere, when in the presence of the ground, and that the stagnation points are not changed by the ground board. Furthermore, the velocity will be greater as the distance, c, between the centers becomes smaller.

The pressure at any point can be determined from the formula,

$$p_n - p_\infty = \rho\,\frac{V^2}{2}\left\{1 - \left[\frac{3}{2}\sin\theta\left(1 + \frac{1}{2}\,\frac{a^3}{c^3} + \frac{1}{4}\,\frac{a^6}{c^6}\right)\right]^2\right\} \tag{19}$$

Points at Which the Tangential Velocity Is Equal to That in the Undisturbed Air Stream.—In the examination of test results, it is of some interest to determine where the tangential velocity is equal to the velocity of the undisturbed air stream. This occurs when $p_n - p_\infty$, as expressed by Equation (6), equals zero; that is, when $\theta = 41.7$ degrees. For the sphere in proximity with the ground, substituting $[1 + K]$ for $\left(1 + \frac{1}{2}\,\frac{a^3}{c^3} + \frac{1}{4}\,\frac{a^6}{c^6}\right)$ in Equation (19), the value of θ will be given by,

$$1 - \left[\frac{3}{2}\sin\theta\,(1 + K)\right]^2 = 0 \tag{20}$$

so that θ will have a smaller value than for the sphere alone.

EXPERIMENTAL METHODS

Model Dimensions and Reynolds Number of the Tests.—The wind-tunnel models of the Perisphere and Trylon were built to a scale of 1 : 100, with only external appearance represented. The main model dimensions were: Sphere diameter, 2.00 ft; height above ground board, 0.08 ft; Trylon height, 6.75 ft; and, Trylon width at the base, 0.68 ft.

In aerodynamic experimentation, scale effects (that is, the difference between air flow over the model and the air flow over the larger full-scale object) must always be considered. The effective scale of the model is represented by the Reynolds number, R, which in the case of the sphere assumes the form,

$$\mathsf{R} = \frac{V\,D}{\nu} \quad \text{(21)}$$

in which V = velocity of the air stream, in feet per second; D = diameter of the sphere; and, ν = coefficient of kinematic viscosity.

The resistance coefficient of a sphere is conveniently represented by the equation,

$$C_D = \frac{R}{\left(\frac{\rho\,V^2}{2}\right)\frac{\pi\,D^2}{4}} \quad \text{(22)}$$

in which R = resistance of the sphere, in pounds; ρ = density of the air $= \frac{\text{specific weight per cubic foot}}{g}$; and, D = diameter of the sphere, in feet.

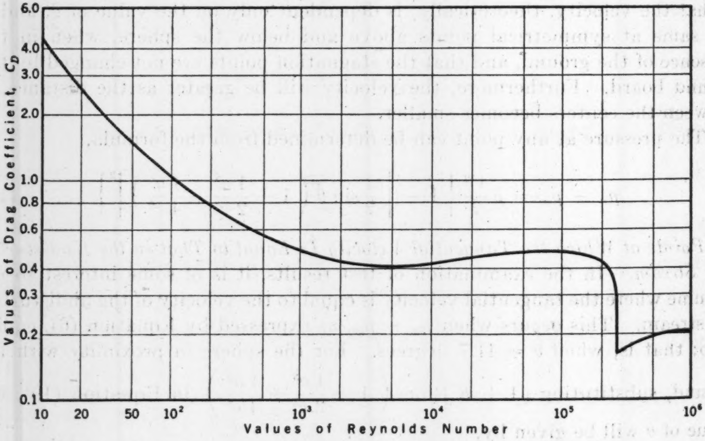

FIG. 4.—VARIATION IN SPHERE DRAG COEFFICIENT WITH REYNOLDS NUMBER

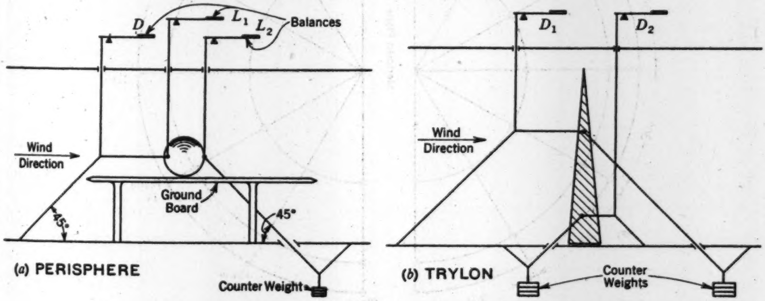
In Fig. 4 the values of the drag coefficients are plotted against the Reynolds number, the curve being obtained from prior tests. It will be seen that, although there is considerable variation in C_D at the lower Reynolds number, the tests at the higher values of **R** are definitely in an asymptotic region. This indicates that the critical region in which the character of the flow changes has been passed, and that the pressure distribution tests, made at an effective Reynolds number of 1 833 880, were definitely in the region where the flow has assumed the character of complete turbulence in the boundary layer. This indicates that the results of the pressure distribution tests may be applied with confidence to full-scale conditions.

It was only possible to make the force tests on the sphere up to a maximum of 30 miles per hr, but in the pressure distribution tests, where it was possible to brace more securely, the indicated air speed of the tunnel was 70 miles per hr, giving a Reynolds number, $\frac{V D}{\nu}$, equal to $6\,378\,(70 \times 1.467) \times 2 = 1\,390\,914$.

The "Effective Reynolds Number" is the best basis of comparison between free air and wind-tunnel results since it includes the effect of the tunnel turbulence, and is defined as the actual Reynolds number multiplied by the turbulence factor which, in this case, equals $1\,390\,914 \times 1.4 = 1\,833\,880$ since the turbulence factor of the 9-ft wind tunnel was 1.4.

Because of the large forces encountered, the drag measurements of the needle were made at lower air speeds than the pressure distribution tests on the sphere, namely 40, 50, and 59.4 miles per hr. Since the needle is not a stream-lined body, its resistance does not change appreciably with the Reynolds number and, therefore, the results of the tests are also applicable to full scale without correction.

Methods of Measuring Air Forces.—The methods of measuring air forces were entirely conventional and are illustrated by Fig. 5. Fig. 5(*a*) shows the sphere suspended in the presence of the "ground board" which was used to simulate the ground effect experienced by the Perisphere. Force tests for the sphere were also made on the same set-up with the ground board removed, to simulate "free air" conditions. With the arrangement shown in Fig. 5(*a*), the sum of the readings of Balances L_1 and L_2 gives the vertical or lift force on the sphere. A sufficiently heavy counterweight is used as shown, so that the wires leading to the lift balances are always in tension. The front wire takes



(*a*) PERISPHERE (*b*) TRYLON

FIG. 5.—SCHEMATIC DIAGRAM OF SUSPENSION SYSTEM FOR FORCE TESTS

up all the drag, and since it is inclined at 45° to the horizontal, the vertical wire running to the front balance, *D*, transmits a force equal to the drag or air resistance. It is clear also that with this arrangement moments can be computed readily about any point. "Tare" measurements and corrections are made without the wind stream, in obvious fashion.

Drag tests of the Trylon, or needle, were run with the needle in the presence, but just free, of the ground, with the tunnel floor representing the ground The special mounting of the Trylon during the drag tests is illustrated diagrammatically in Fig. 5(*b*).

The vertical center of pressure (point of application of resultant drag force) is determined by obvious calculation when the forces in the two drag wires and their points of application are known.

Measurement of Pressure Distribution on Sphere, (2), (3).—The pressure distribution was measured on one hemisphere only as it may be assumed that the air flow is symmetrical about a plane through the center of the sphere, normal to the ground line and parallel to the direction of the air stream. This system was particularly convenient inasmuch as it permitted one-half the sphere to be free of pressure orifices, thus leaving a clear space for the exit of the pressure tubes, and avoiding flow disturbing influences.

The pressures on the surface of the hemisphere were measured at thirty-seven points disposed as follows (see Fig. 6): All pressure holes lay on the surface of the sphere along the traces of great circles cut by planes passed through the center of the sphere. The "meridian," or VI-XII, circle was the trace of a vertical plane passed through the center and two poles. When the

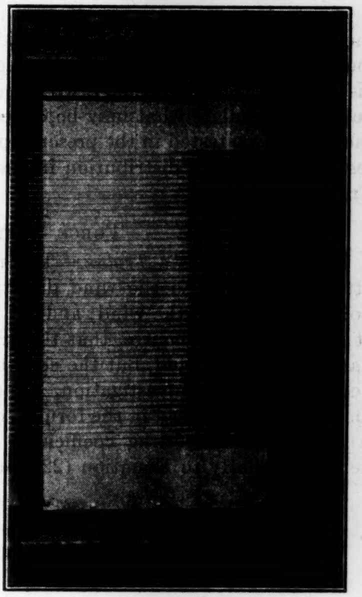

FIG. 8.—MULTIPLE MANOMETER FOR PRESSURE MEASUREMENT

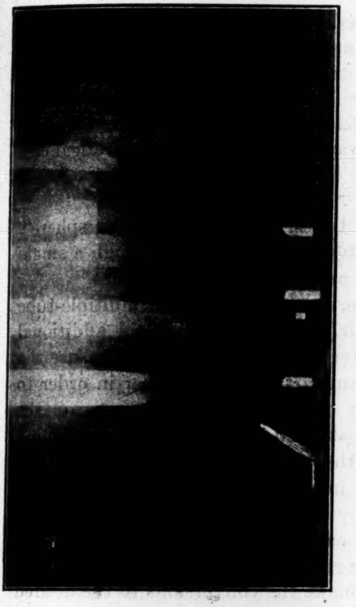

FIG. 9.—SPHERE ON COLUMNS

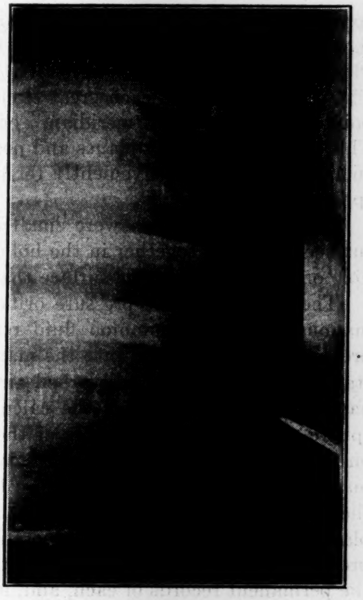

FIG. 10.—SPHERE ON COLLAR

sphere was mounted in the tunnel this "meridian" plane was coincident with the vertical plane of symmetry of the tunnel. The planes designated as Planes I, II, III, IV, and V were all at 30° intervals from the "meridian" plane. The pressure holes on each great circle were placed at 30° intervals, with two points common to the "meridian," or VI-XII, plane and to all other planes. This system of defining planes and points was selected because theoretical calculations are made conveniently for points thus arranged on the surface of a sphere.

The pressure orifices were small brass tubes, set flush with the sphere's surface, gathered together in the hollow interior, and led out through a single hole on the far side of the surface that did not contain pressure holes.

The leads from the pressure orifices were connected to the multiple-tube manometer with a common fluid reservoir. There were several additional pressure leads connected into the manometer which were used to measure the static pressure of the undisturbed air stream in the test chamber in order to have a basic reference for the calculation of the absolute pressures on the sphere surface. The pressures of the undisturbed air stream were measured on the sides of the channel well ahead of the position of the sphere. A permanent record of the fluid-pressure heads indicated by the colored liquid in the glass manometer tubes was obtained by means of positive printing paper placed behind the tubes and exposed to a carbon arc light. The use of this procedure made it quite a simple matter to run a series of pressure tests, take the permanent records of each, and, later, make the conversions to the desired pressure units.

Fig. 7 shows the general arrangement of the model in the wind tunnel; Fig. 8, the multiple manometer set-up outside the tunnel; Fig. 9, the model on the four-column supports; and Fig. 10, the model on the collar support. Pressure distribution tests were made with the sphere suspended without the ground board (to simulate what may be called "free air conditions"). Subsequently, the sphere was tested in the presence of the ground board; in other runs, it was tested for pressure distribution in the presence of the ground board and the Trylon combined.

FORCE TESTS ON TRYLON

Drag Tests on the Trylon.—The tests on the Trylon were made in two attitudes relative to the wind direction (see Fig. 11): (1) With one of the pointed edges into the wind; and (2) with one of the flat sides into the wind. It was realized, of course, that the greatest air resistance would occur with a flat side into the wind, but the condition of a pointed edge into the wind was deemed worthy of investigation. The results of the drag tests on the Trylon may best be expressed in the form of coefficients of drag, as exemplified by the American absolute drag coefficient, C_D, of aeronautical practice, which is defined similarly to Equation (22) for the sphere, namely,

$$C_D = \frac{D}{\left(\rho \frac{V^2}{2}\right) S} \quad \ldots\ldots\ldots\ldots\ldots\ldots (23)$$

in which S = the area of a flat side projected on a vertical plane, in square feet. Although the drag tests of the Trylon were run at several tunnel air speeds, the coefficients for all speeds were sufficiently close to permit an average value to be chosen for each of the two attitudes tested. This coincidence of values had been expected on theoretical grounds. The values are:

Attitude of Trylon	Drag Coefficient, C_D
Pointed edge into wind	0.879
Flat side into wind	1.433

They substantiated the anticipation that the Trylon with the flat side into the wind would show the greater drag, since the body with an edge into the wind is really of crudely semi-streamlined form, whereas with the flat side into the wind the flat-plate effect is predominant. The accepted coefficient for the flat-plate drag is $C_D = 1.28$, as used in aeronautical engineering practice. The value obtained for the Trylon with the flat side into the wind is $C_D = 1.433$, about 12% greater than for the flat plate alone. The difference between the two may be justified in view of the fact that the Trylon, being a solid of three dimensions, presents some surface area to the wind stream, so that, in addition to the flat-plate drag effect, there is a drag due to the surface areas of the body, with the probability of turbulent flow on the two down-stream sides.

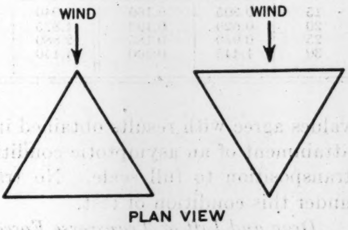

FIG. 11.—TWO POSITIONS OF TRYLON RELATIVE TO WIND

The center of pressure position of the drag forces acting on the Trylon, with a flat side into the wind, was shown to be at an average value of 28.50 in. from the base and along the vertical axis. This point too seems logical since it is within 1.5 in. of the centroid of area of the vertically projected triangle of a flat side of the Trylon.

The full-scale air resistance or drag and upsetting moment about the base of the Trylon may be computed easily for any given air speed by substitution in Equation (23) for the solution of force, and the moment by the usual formula, in which the center of pressure position shown by the tests would be used as the moment arm. If it is assumed that the air speed is 100 miles per hr, the value, $C_D = 825\,000$ lb, would be obtained for the full-scale body with flat side into the wind, and an area projected on the vertical of 22 500 sq ft.

The wind load at 100 miles per hr is thus seen to be 36.6 lb per sq ft of projected area. For buildings higher than 100 ft the Building Code ordinances of New York, N. Y., call for an assumed wind pressure of 20 lb per sq ft of exposed surface from the top of the building down to the 100-ft level. If the flat-plate coefficient of 1.28 is used, this is equivalent to 78 miles per hr. The results of the tests on the Trylon, computed for a wind of 78 miles per hr, would show a loading of about 22.3 lb per sq ft for the entire length of the projected area.

FORCE TESTS ON THE PERISPHERE

Drag Tests in Free Air.—The coefficients of drag, C_D, for the free air test (that is, without the presence of the ground) are given in Table 1(*a*). These values agree with results obtained in other laboratories, and they indicate the attainment of an asymptotic condition of flow which is not greatly altered by transposition to full scale. No transverse or lift force is found, of course, under this condition of test.

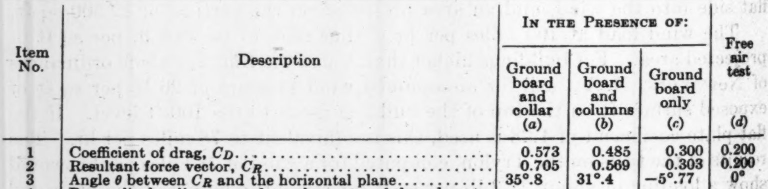
Drag and Lift or Transverse Force Tests in the Presence of Ground Board and Collar, and of Ground Board and Columns.—In these tests the sphere was supported by wires from the balances in the manner described under the heading, "Experimental Methods," with just sufficient clearance between the sphere and the collar, and the sphere and columns, to permit force measurements to be made. The results of these measurements are given in Table 1(*b*) and Table 1(*c*) and in the vector diagrams of Table 2 which indicate the direction

TABLE 2.—FORCE VECTORS ON PERISPHERE, AT 30 MILES PER HOUR



Item No.	Description	IN THE PRESENCE OF: Ground board and collar (*a*)	Ground board and columns (*b*)	Ground board only (*c*)	Free air test (*d*)

4	Perpendicular distance, *e*, from the center of the sphere to C_R, in inches	0.30	0.27	0.24	0

of the resultant force. This resultant force is expressed in coefficient form as C_R, the coefficient being defined by an equation similar to that used for C_D (see Equation (23)), but with the resultant force, R, used instead of the drag, D. The resultant force has been calculated in the usual manner from the drag, D, and the transverse or lift force, L.

It is clear that the introduction of the ground board and the collar, or of the ground board and columns, serves to produce an appreciable transverse force in an upward direction—that is, a "lift" in aeronautical terminology. The production of such transverse forces is readily explainable. The introduction of the collar below the sphere naturally retards the flow on the lower surface, and also removes suction effects over a considerable part of the lower area. The presence of the column produces a similar effect but not to so large an extent, and hence the resultant vector is less inclined away from the horizontal in the case of the columns, than in the case of the collar, which blocks the air flow so effectively. It will also be noticed that for the sphere in the presence of the ground only (that is, without collar or columns (Table 2(*c*)), the transverse force is small, but in a downward direction as shown by the resultant force vector which points downward. It is apparent that for this case the air flow is speeded up between the ground board and the lower half of the sphere giving rise to high suction effects in this region and, hence, a downward or negative lift force.

The foregoing conclusions seem to be substantiated by the pressure distribution tests for all the cases, the results of which are given subsequently under the heading, "Pressure Distribution Tests on Sphere." The transverse forces are probably of little importance to the structural engineer. It is most interesting, however, to compare the drag coefficients under the various conditions of the test (see Item No. 1, Table 2).

The great increase in the drag is explainable partly by the increase in speed over the surface of the sphere when in the presence of the ground (as indicated under "Theoretical Considerations" and substantiated by the pressure distribution tests), partly by the general disturbance of the flow due to the obstructions, and partly by the additional or induced drag which follows on the production of lift.

From a structural engineer's point of view it is important to note that wind forces on the sphere are greater in the case of the collar than in the case of the columns, although even in the very worst condition the direct drag force on the sphere is less than one-half the force that would be experienced on a flat plate of the same area as the projected area of the sphere.

PRESSURE DISTRIBUTION TESTS ON SPHERE

The following pressure distribution tests were run:

Test No.	Description
1	Free air test of sphere alone.
2	Sphere alone in the presence of the ground board.
3	Sphere on four columns, 1 in. in diameter, with ground board.

Test No.	Description
4	Sphere on collar, 8 in. in diameter, with ground board.
5	Sphere on collar, with ground board and with the Trylon 25 in. on one side.
6	Sphere on collar, with ground board and with the Trylon 25 in. in front.

The distance of 25 in. was measured from the center of the base of the Trylon to the center line of the sphere as shown in Fig. 1. The results of these pressure distribution tests are best shown by the diagrams in Figs. 12, 13, and 14. The pressure distribution diagrams for all the tests are plotted around 360° for the meridian plane (VI-XII) and around 360° for the equator plane (III-IX). In addition, corresponding diagrams have been plotted for Planes I-VII and II-VIII for the test of the sphere alone in the presence of the ground board, so that the pressure distribution over the entire sphere is represented for that case as shown in Figs. 13(*a*), 13(*b*), 13(*c*), and 13(*d*).

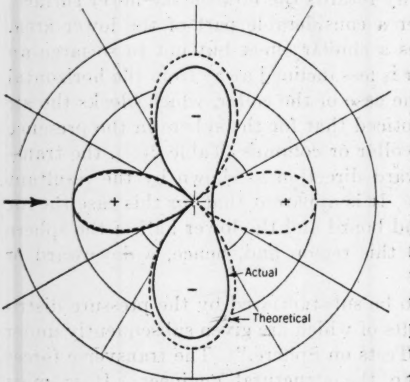

FIG. 12.—PRESSURE DISTRIBUTION OVER ANY GREAT CIRCLE PLANE OF SPHERE IN FREE AIR

The method of plotting the results of the pressure distribution tests utilizes a form of polar diagram in which the wind direction is indicated by the heavy arrow, the radial lines, the 30° divisions, on which the pressures were measured, and the concentric circles, represent radii of $\left(\frac{p_n - p_\infty}{\rho \frac{V^2}{2}}\right)$ equal to 0.5, 1.0, and 1.5, respectively. The expression, $\frac{p_n - p_\infty}{\rho \frac{V^2}{2}}$, is the same as that used in Equation (19). The test data were reduced to this pressure-unit ratio because it is non-dimensional and, therefore, will be the same for all velocities beyond the critical range. It will be noted that on the pressure plots certain parts of the distribution curves are marked plus (+) and others minus (−). The plus (+) sign means that the pressure-unit ratio was positive, thereby indicating a region of positive pressure acting normal to the sphere surface; and, the minus (−) sign shows the negative pressure or suction area normal to the sphere surface. Pressures, of course, are referred to the static pressure of the undisturbed air stream as a base.

Under the heading, "Theoretical Considerations," the flow for a perfect fluid was investigated for the cases of the free-air sphere, and for the sphere in

the presence of the ground board. The pressure ratios have been computed by Equations (6) and (18), and it is interesting at this point to compare the theoretically calculated and the measured pressures over the sphere. Therefore, in Figs. 12, 13(*a*), 13(*b*), 13(*c*), and 13(*d*) the measured pressures are shown by the full line and the theoretical pressures by the dotted line.

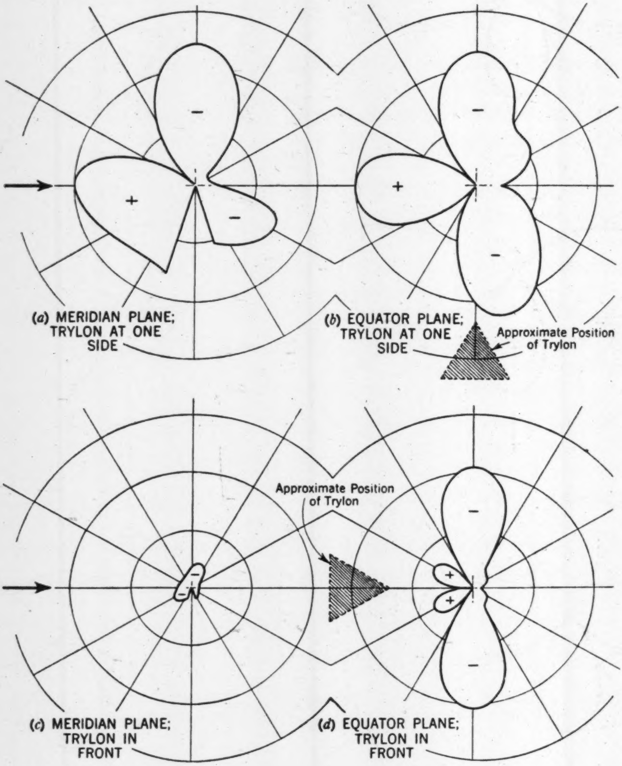

FIG. 14.—PRESSURE DISTRIBUTION OVER THE SPHERE; IN THE PRESENCE OF TRYLON, GROUND BOARD, AND COLLAR

Sphere in Free Air.—An examination of the pressure diagram for the free-air sphere (Fig. 12) reveals that the computed and measured pressures are in excellent agreement for the area included between about ±60° either side of the horizontal plane of symmetry on the windward side. It will also be observed that on the windward side of the sphere, the points where the tangential velocity is equal to the undisturbed air stream velocity (or where the pressure ratio is equal to zero) check for both the calculated and measured pressure patterns. At the rear of the sphere surface the theoretical pressures for a perfect fluid have the same positive values as for the corresponding area on the front. The measured pressures on the rearward side of the sphere show that, instead of a region of positive pressures which would be present in a perfect fluid, there is a region of negative pressures. This discrepancy may be explained as follows: In a perfect fluid such as was assumed for the theory, the flow around any great circle of the sphere would be symmetrical. If this were so, the symmetrical pressure distribution diagram indicated by the dotted lines of Fig. 12 would be obtained and the sphere would have zero drag or resistance. In the imperfect fluid that air is, this ideal condition cannot be realized as the air moves over the sphere surface with viscous drag, with the building up of a boundary layer; ultimately, the tearing away of the boundary layer on the rear half; the creation of an eddying region; and, consequently, a drop in pressure behind the sphere. This actual flow is represented diagrammatically in Fig. 15. It is interesting to note that the maximum suction developed experimentally is somewhat greater than the theoretically calculated value. This does not necessarily indicate that the tangential velocity is higher, since loss of pressure is experienced due to viscosity.

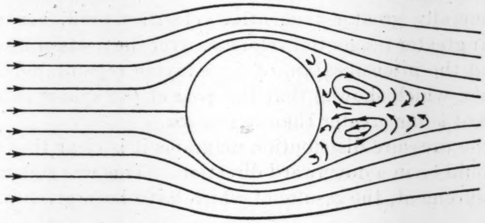

FIG. 15.—DIAGRAM OF ACTUAL AIR FLOW AROUND A SPHERE

Sphere in Presence of the Ground.—The comparison of the theoretically calculated and measured pressures for the sphere in the presence of the ground board is shown in Figs. 13(*a*), 13(*b*), 13(*c*), and 13(*d*) in four plots so that all the great circles used are represented. The plots show that the theoretical and measured pressures agree very well for the part of all the great circles that is on the upper forward half of the sphere. In this region too, the points at which $\left(\frac{p_n - p_\infty}{\rho \frac{V^2}{2}}\right) = 0$ are in good agreement for both the theory and practice. On the rear half of the sphere the same general discrepancies are noted as were shown for the free air sphere. The most interesting points in the comparison occur on the lower side of the sphere that is in close proximity with the ground board. Here, it will be seen that the greatest difference between theory and measurement is shown for the meridian plane and the least for the equator plane. Upon following the general effects on all planes from the lower half of the meridian up to the equator, it can be seen that the discrepancies between theory and measurement tend to lessen progressively. The general conclusions that might be drawn from the measured pressure distribution diagrams are:

(1) Hydrodynamic theory indicates that, in a perfect fluid, the presence of the ground board should cause a greater tangential velocity over the entire

surface of the sphere, and not only on the lower part of the sphere near the ground board. A study of the suctions in Figs. 12, 13(*a*), and 13(*b*), indicates that experiment is in accord with the theory.

(2) On the lower half of the sphere, in the presence of the ground board, there is greater discrepancy between theory and experiment. A boundary layer is built up over the ground board within which the air is retarded. This is equivalent to a construction of the air passage between sphere and ground, and explains the much higher velocity on the lower part of the meridian plane. Figs. 13(*a*) and 13(*b*) indicate that the maximum suction attains relatively very high values. For points that are farther away from the direct influence of the ground this effect is lessened.

(3) The presence of the ground board intensified the eddying region at the back of the sphere, on its lower half.

(4) The generally greater tangential velocities (and, hence, greater skin friction), the far greater tangential velocities over the parts of the sphere nearest the ground, and the intensification of the eddying regions, confirm the results of the drag tests, which showed that the drag of the sphere in the presence of the ground board is far greater than in free air.

(5) From the pressure distribution diagrams it is clear that the transverse, or lift, force would be in a downward direction. This was shown to be the case by actual measurement, the results of which have been given in Table 2.

Sphere in Presence of the Ground and Collar, and in Presence of Ground and Columns.—The pressure distribution diagrams for a sphere in the presence of a ground board and a collar, and in the presence of a ground board and columns, are plotted in Figs. 13(*e*), 13(*f*), 13(*g*), and 13(*h*) for the meridian and equator planes only. These two planes or great circles were chosen as being the most representative. Study of the diagrams of Figs. 13(*e*), 13(*f*), 13(*g*), and 13(*h*) leads to the following conclusions:

(6) The introduction of either the collar or the column changes the character of the flow appreciably on the meridian plane. The positive pressures on the meridian plane at the windward side of the sphere now extend far below the equator. The introduction of either columns or collars impedes the flow, as would be expected, and hence creates the pressure region. The production of pressure below the equator explains the fact that the transverse force or lift on the sphere is now upward, as shown by the force tests.

(7) The introduction of both the collar and the columns disturbs the flow considerably and produces intensification of the eddying region at the back of the sphere, below the equator. This explains the production of a new region of suction which was not present in the case of the sphere in free air, or in the presence of the ground.

(8) At and above the equator, the pressure distributions in the presence of the ground and in the presence of the ground and collar, or column, are very similar. It is on the lower half of the sphere that the introduction of the collar or a column produces the most marked effects.

(9) The intensification of eddying and the production of a new region of suction when a collar or column is introduced explain, adequately, the greater drag of the sphere as compared with its drag in the presence of the ground alone.

(10) The introduction of the collar affects the drag and pressure distribution far more than the introduction of the columns, which still provide a passage for air flow close to the ground. From the point of view of structural loads, mounting on columns is preferable to mounting on a collar.

(11) The introduction of the collar or column produces great asymmetry of pressure on the meridian which the structural engineer would no doubt take into account, taking care to examine local effects.

Sphere on Collar with Trylon at Side.—The pressure diagrams of Figs. 14(*a*) and 14(*b*), illustrating the aforementioned condition, constitute a composite diagram for the equator plane, since only 180° of the equator plane was provided with orifices. In plotting the pressure at the equator plane the 180° on the Trylon side was obtained from actual observed data. On the far side of the equator plane away from the Trylon, data were taken from the test with collar but no Trylon, the assumption being that the presence of the Trylon would not appreciably affect the pressure distribution on the far side.

The introduction of the Trylon on the side does not cause marked variations in the pressure distributions. A twisting moment about the vertical axis of the sphere would be introduced, but this should not be serious.

Sphere with Collar and Trylon Ahead.—The pressure distribution for this case is illustrated in Figs. 14(*c*) and 14(*d*). The Trylon acts very powerfully as an aerodynamic shield. On the meridian plane pressure effects practically disappear, with all the orifices under a very slight degree of suction. The shielding effect on the equator plane is very marked. The pressure on the windward side of the sphere almost disappears, and the suction diminishes to a value of $\left(\frac{p_n - p_\infty}{\rho \frac{V^2}{2}}\right) = -1.0$ (approximately).

General Conclusions

From the point of view of the structural engineer some general conclusions appear to be of interest:

(12) For even a semi-stream-lined object, such as a sphere, it is impossible to design for air loads on the basis of some empirical rule for wind pressure. The same point of the structure may, at one time, attain a maximum pressure, and, at another time, a high suction value.

(13) Intense variation in pressure differences from point to point must be expected and allowed for in design.

(14) Instead of endeavoring to apply general rules, a systematic survey of pressure distribution is necessary, with subsequent integration of loads along planes in three directions, and integration of local load distribution. It is understood that Shortridge Hardesty, M. Am. Soc. C. E., has made use of the data herein presented for the most painstaking load integrations.

(15) The heaviest loads will be encountered when the Trylon is at the side of the sphere when the wind is considered as striking the nose of the sphere.

(16) The only points that will always be in high suction are those toward the upper surface of the sphere.

(17) The shielding effect of the Trylon should be taken into consideration with saving in weight of certain members.

(18) In general, structural members would have to withstand tension and compression loads under different wind conditions.

(19) The maximum positive pressure will be experienced at the equator and will never exceed $\left(\frac{p_n - p_\infty}{\rho \frac{V^2}{2}}\right) = 1.0$.

(20) Since the static pressure inside the sphere should be about equal to the outside static pressure it is inconceivable that pressures in excess of those shown in the pressure diagrams should ever exist. This being the case, and if 100 miles per hour is assumed as the maximum possible outside air velocity, then the maximum positive pressure on the sphere would be 25.6 lb per sq ft, and the negative pressure about −30.8 lb per sq ft on the sides of the equator plane.

ACKNOWLEDGMENTS

The investigation reported herein was undertaken at the request of the Construction Department of the New York World's Fair Corporation. For their active co-operation, thanks are due especially to John P. Hogan and L. B. Roberts, Members, Am. Soc. C. E., Chief Engineer and Assistant Chief Engineer, respectively, of that organization. Thanks are also due to Mr. Hardesty for his critical guidance in the conduct of the experimentation. All the major and auxiliary apparatus in the laboratories of the Daniel Guggenheim School of Aeronautics, College of Engineering, New York University, was made available for this purpose.

DISCUSSION

Elliott G. Reid,[5] Esq. (by letter).—It is the writer's opinion that several phases of the work reported in this paper should not be allowed to pass unchallenged.

The theory presented is not only inapplicable but highly misleading. To be sure, the distribution of pressure over a large part of the surface of a sphere which moves through an unlimited mass of air is satisfactorily predicted by the methods of classical hydrodynamics. Therefore, determination of the velocity potential for the motion of a sphere parallel to a plane boundary might be expected to enable qualitative determination of the boundary interference effects. However, the mathematical complexity of this problem is so formidable that Lamb[6] gives only "the first steps in the approximation" and, of course, not even Neumann's[7] rigorous solution covers the practical problem which is further complicated by interference effects arising from the foundation structure of the Perisphere. These facts would seem to justify, if not to compel, the omission of all but qualitative theoretical treatment.

Nevertheless, the authors actually present a substantial reproduction of Lamb's approximate solution—which is entirely inapplicable when the sphere is close to the boundary surface. It appears that the significance of the substitution of c^3 for r^3 has escaped them because they conclude (following Equation (18)) that "the velocity, theoretically * * * is the same at symmetrical points above and below the sphere, when in the presence of the ground," and that "the stagnation points are not changed by the ground board." Inspection of the potential flow pattern for this case[8] demonstrates not only that both conclusions are unfounded but that the experimental results (Fig. 13(*a*)) are in qualitative agreement with hydrodynamic theory.

The significance of the results of force and pressure distribution tests on the Perisphere is highly questionable because the authors' interpretation of Fig. 4 is not justifiable. They err first by assuming the numerical values to be correct. The important portion of the curve (that is, that for which $R > 3 \times 10^5$) is substantially that determined by Wieselsberger[9] who supported his spheres approximately as illustrated by Fig. 5. The importance of the interference effects which characterize such installations was first demonstrated by the writer[10] in 1923; subsequent investigations by Wieselsberger[11] and Flachsbart[12] confirm his findings and thus invalidate that part of the curve upon which the authors predicate their extrapolation of model test results to full scale. According to the most reliable information available,[13] the value of C_D at $R_e = 750\,000$ is about one-half that shown by Fig. 4. Even more important, however, is the authors' erroneous assumption (also based on Fig. 4) that an unchanging flow pattern exists at all values of R_e greater than 1 400 000. The fallacy is exposed by Jacobs' tests[13] which show that C_D increases continuously while R_e varies from 1 400 000 to 2 600 000. (It is noteworthy that in the case of the full-scale Perisphere the value of R_e would be 140 000 000 at a wind speed of 70 miles per hr.) Since neither theory nor experiment justifies such procedure, use of the unaltered model pressure data for "the most painstaking load integrations" seems likely to prove love's labor lost.

Discussion of the pressure distribution tests would be incomplete without reference to the explanation which appears in the last two sentences under "Pressure Distribution Tests on Sphere: Sphere in Free Air." The authors appear to have explained a non-existent phenomenon, that is, in Fig. 12, the maximum suction developed does not exceed the calculated value.

Turning now to the Trylon, if that were to be an isolated structure and if the variation of wind speed with height were unimportant, the model test results might provide a rational basis for estimating the total wind loads on the full-scale structure. However, since the interference of the adjacent Perisphere would undoubtedly modify—and, with some wind directions, would probably augment—these forces, the omission of interference tests makes the validity of the recorded results somewhat dubious. No occasion for surprise is evident in the result, $C_D = 1.433$; narrow rectangular plates have long been known to experience relatively large resistances. Finally, since information concerning the distribution of wind loads was sought, it seems regrettable that tests were not made to determine the severity of the pressure gradients near the edges of the Trylon.

Karl Arnstein,[14] **Esq.** (by letter).—The wind tunnel tests and theoretical consideration of models of the Perisphere and Trylon that the authors are making add more light to the problem of designing structures of unusual nature to withstand aerodynamic loads. These tests are interesting to the writer because they are somewhat parallel to problems encountered in designing the large airship hangar at Akron, Ohio, for which the senior author conducted wind tunnel tests on a hangar model which were later confirmed to a very reasonable degree by full-scale tests made at a later date on the hangar itself. These full-scale tests and related design considerations have been published.[15]

There is one conclusion made by the authors which should be scrutinized more closely. In Conclusion (20) it is suggested that the static pressure inside the sphere should be about equal to the outside static pressure. In large buildings such as the Perisphere or an airship hangar, ample ventilation must be provided to accommodate changes in temperature and barometric pressure and for other considerations. For any static loading condition the internal static pressure of the building must equal the local pressure at the ventilator or other openings, such as doors, which, in turn, must correspond to the local external pressure at that point. Since the external pressure pattern may change greatly for any fixed point on the surface of the building, depending on the direction of the wind, it is difficult to imagine the internal pressure remaining at any constant value.

[15] "Wind Pressures on the Akron Airship Dock," by K. Arnstein and W. Klemperer, *Journal of the Aeronautical Sciences*, January, 1936.

In the case of the airship hangar it was assumed that the internal pressure could vary from the greatest ventilating suction to the greatest over-pressure to be expected from any local opening.

W. B. KLEMPERER,[16] ESQ. (by letter).—The subject of the paper is of interest to the aeronautical engineer especially because of its close analogy with the problems arising from the groundhandling of large free balloons. Every opportunity to supplement theoretical investigations with experimental research, therefore, is keenly appreciated.

The approximate theoretical treatment of the Perisphere in representing the effect of a mirror image sphere by a mere increase of the axial doublet strength, as adopted in the paper, is a close approximation only where the ground distance is large compared to the radius. However, the closer the ground distance the poorer the approximation becomes. It neglects the flow constraint near the ground and leaves no room for any vertical force acting on the sphere without pedestals.

With the ground clearance only a small fraction of the radius, the first-order mirror doublet almost doubles the velocity increment at the bottom of the sphere, whereas it contributes only about 4% at the top. The body generated by a space doublet does not stay spherical when the flow of a parallel mirror doublet in its proximity is added to a general parallel flow.

Therefore, the observed vertical nonsymmetry of the pressure distribution need not be interpreted as a discrepancy between theory and experiment. Thus the high suction observed in the bottom region may not all be due to the ground board's boundary layer restricting the passage, as was suggested in Conclusion (2), but also to a genuine Venturi effect which can be embraced by a classical theory taking the nonsymmetry of the mirror-flow system with respect to the sphere center level into account.

Such a theory requires the introduction of successively mirrored doublets, or sources and sinks, eccentrically located in the spheres. Lamb postulates an attraction between the sphere and the ground, for the ideal fluid.[17]

The fact, however, remains that as soon as circulation is created about the sphere by ground surface friction, etc., a lift force is generated which may outweigh the Venturi attraction. The same effect may be caused by a large-scale wind boundary layer extending high above the sphere, much larger than would correspond to the relatively thin boundary layer adjoining the ground board in the wind tunnel. The real sphere, therefore, may have a greater lift than the model. This additional lift could be expected to be essentially proportional to the average vertical wind gradient throughout a layer comparable in thickness to the height of the structure.

The question of what pressure will actually prevail inside the spherical building would appear to be worth while to answer by full-size experiment. The tendency to keep out draft favors leeward ventilation and most likely works toward lowering the interior pressure below atmospheric static. An exposition building of this kind might lend itself to the installation of recording gages.

RELATION OF RAINFALL AND RUN-OFF TO COST OF SEWERS

BY JOHN A. ROUSCULP,[1] ASSOC. M. AM. SOC. C. E.

SYNOPSIS

The preliminary design of storm sewer systems often requires a number of laborious studies involving various plans and perhaps various combinations of the two design factors—rainfall frequency rates and run-off percentage. It is the purpose of this paper to describe the development of a method, using time-saving charts, based on a study of relative costs of a system, which can be a valuable aid in preliminary design work.

The relative costs of storm sewers, as studied herein for various combinations of design factors, are based on the application of such combinations to an assumed district. The selection of this assumed district was based upon a study of the concentration of area of a number of actual districts.

The rational method of estimating run-off was used in computing the various cases. Explanation is made of the method of determining the assumed district, and a sample computation is given to illustrate the method of determining the run-off, Q, for one of the cases. The results of the run-off Q-computations for all cases are plotted on charts showing the run-off, Q, for corresponding area. These charts are used as the basis for computing relative sewer-capacity requirements in connection with the study of cost relations. A discussion of results is given, together with examples suggesting some practical uses of a study of this nature.

The writer does not intend that the charts, as developed, should cover the full range of design stipulations that may be encountered, or be of widespread applicability. Rather, it is hoped that the development, as a method, may be helpful to other engineers in making similar studies to satisfy various special requirements.

INTRODUCTION

In the design of storm-sewer systems, the run-off at various points and the cost are dependent on the values adopted for the rainfall frequency rates and the run-off percentage. The use of various values for either or both of these

---

NOTE.—Published in June, 1938, *Proceedings*.

[1] Senior Designing Engr., Div. of Eng., City of Columbus, Columbus, Ohio.

design factors will result in corresponding values of computed run-off and cost. In order to study the effect of such design factors it is necessary to re-compute the entire system for each set of values. For example, suppose a design has been made on the basis of 10-yr rainfall and 40% run-off, and the cost estimated. Then, if for some reason, the estimated cost on a design basis of a 5-yr rainfall and 30% run-off is required, the system must be re-computed entirely. The relations of run-off and cost resulting from the use of various combinations of design factors as determined by this study can be used to determine such relative cost quickly, and to lessen the computing work greatly. Hence, the results of this or similar studies should be especially useful to engineers when confronted with preliminary design problems of this kind. Clearly, with such a quick means of estimating the relative costs, more thorough and comprehensive preliminary studies would be possible. Since it was necessary to vary slope and area to determine the effect of the rainfall and run-off factors, it was convenient to analyze also the relative effect of the slope and area factors on run-off and cost.

SELECTION OF TYPICAL DISTRICT

As a guide in the selection of the typical district, several representative sewer districts were used (see Fig. 1). The area concentrating and time of concentration, in minutes, were computed for a number of collection points along the main trunk sewer in each district. The areas concentrating for each district were then plotted in Fig. 2, and a curve for each district was drawn.

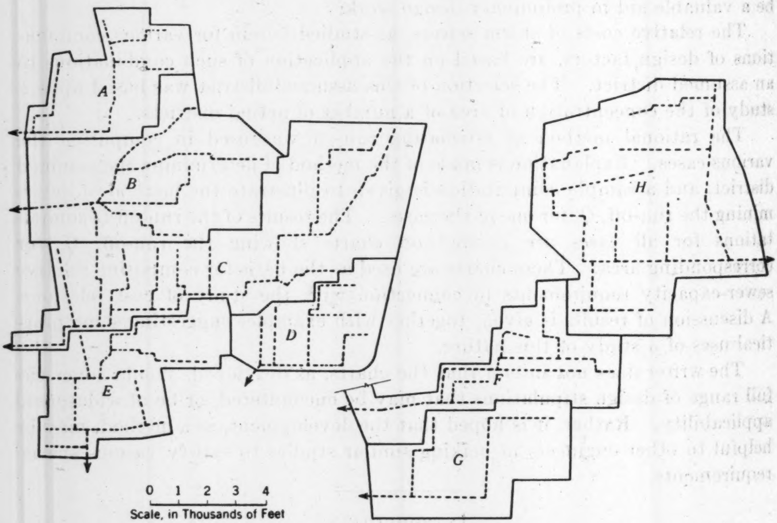

FIG. 1.—OUTLINE OF VARIOUS DISTRICTS USED IN STUDY OF CONCENTRATION OF AREA, SHOWING LOCATION OF PRINCIPAL SEWERS

A smooth curve, which was assumed to represent approximately an average of the curves of the various districts, was then drawn. This average curve represents the typical district, and areas concentrating with respect to time, as given by this curve, are as follows:

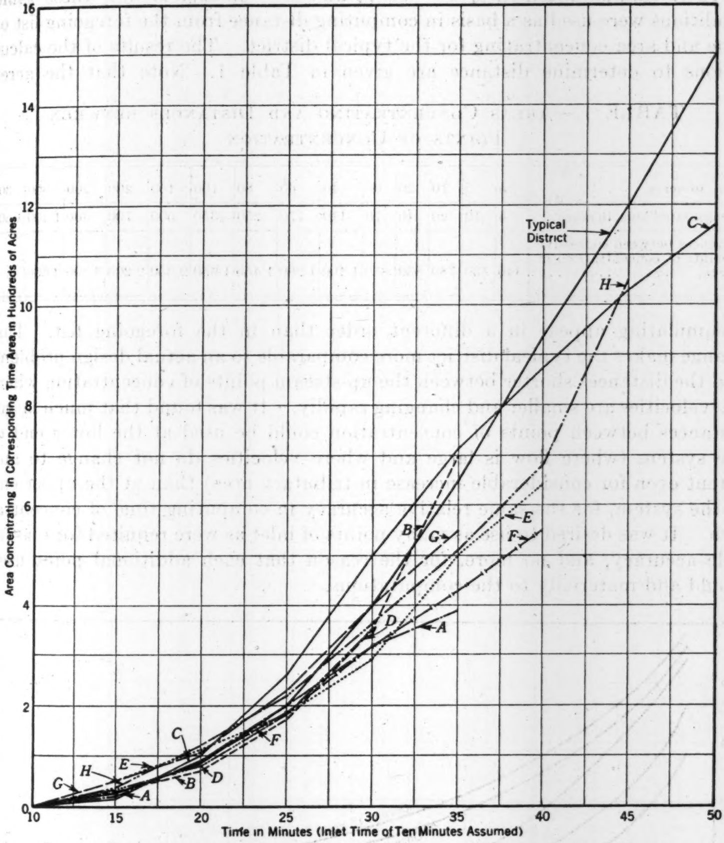

FIG. 2.—CONCENTRATION-OF-AREA CURVES OF VARIOUS DISTRICTS USED AS GUIDES IN SELECTING TYPICAL DISTRICT

Time, in minutes (based on $S = 0.003$)	Area, in acres, used for typical district	Time, in minutes (based on $S = 0.003$)	Area, in acres, used for typical district
15	25	35	650
20	80	40	940
25	200	45	1 200
30	400	50	1 500

The next step was to convert time in the typical district to distance, since the element of distance between points of concentration is necessary in a design problem. In computing the time element for the representative districts, velocity was based on sewer sizes required when using a design basis of 10-yr rainfall intensities, $C = 30\%$, and $S = 0.003$. Hence, these same conditions were used as a basis in computing distance from the foregoing list of time and area concentrating for the typical district. The results of the calculations to determine distance are given in Table 1. Note that the acres accumulating appear in a different order than in the foregoing list. This change makes the typical district more comparable to an actual design problem, and the distances shorter between the up-stream points of concentration where the velocities are smaller and changing rapidly. It was found that much larger distances between points of concentration could be used at the lower end of the system (where flow is large and where velocities do not change to any extent even for considerable increase in tributary area) than at the upper end of the system, for the same relative accuracy in computing time of concentration. It was desired to use as many points of inlet as were required for reasonable accuracy, and no more, for the reason that each additional point used would add materially to the computations.

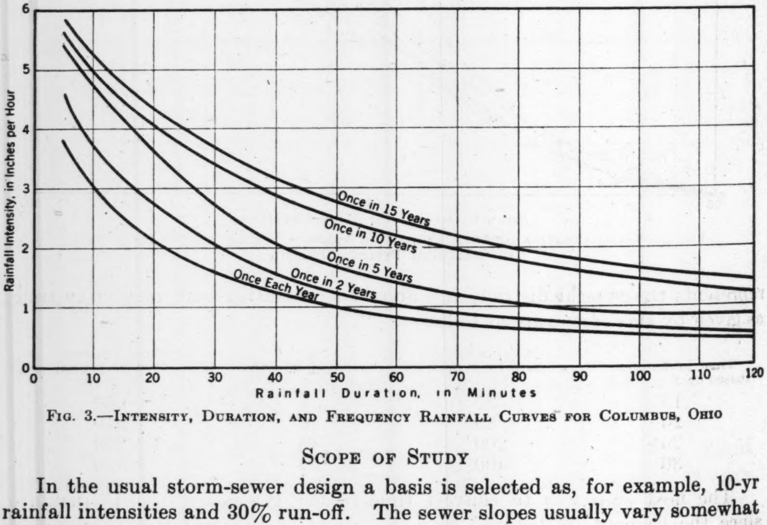

FIG. 3.—INTENSITY, DURATION, AND FREQUENCY RAINFALL CURVES FOR COLUMBUS, OHIO

SCOPE OF STUDY

In the usual storm-sewer design a basis is selected as, for example, 10-yr rainfall intensities and 30% run-off. The sewer slopes usually vary somewhat in each separate problem, and, hence, slope is not a part of the design basis. In this study, however, four different slopes were used, principally to determine whether the relative results due to the rainfall and run-off factors were affected by the slope factor. The range of factors covered in this study are presented in Table 2.

TABLE 2.—RANGE OF FACTORS COVERED BY STUDY

Rainfall intensities, yearly bases	10	5	2
Run-off percentages	30	40	50
Slopes	0.001	0.003	0.01 and 0.02

The total number of possible combinations of these factors is 36, and, hereinafter, they are referred to as cases. Hence, 36 sets of computations were made, using the typical district areas and distances, as given in Table 1. The rainfall intensities used are given in Fig. 3. Table 3 is an example of the computation to determine the run-off, Q, for one of the 36 cases. The values of Q thus determined for all 36 cases were summarized and plotted on Fig. 4.

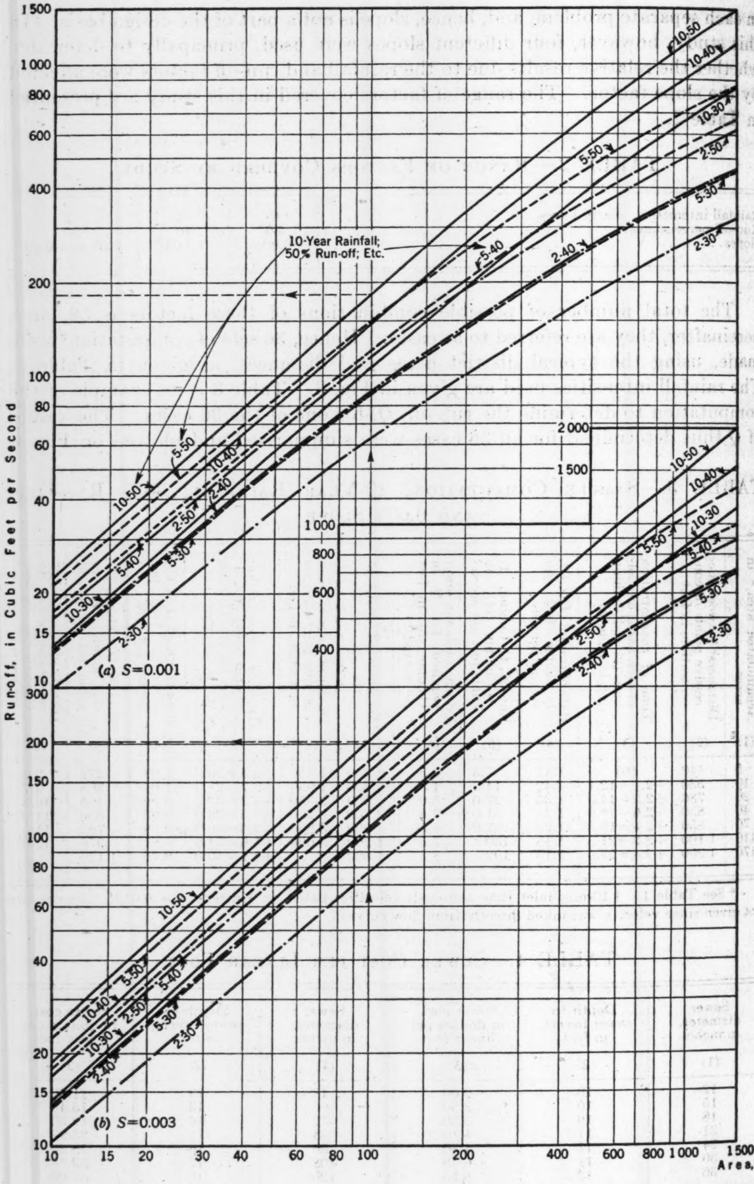

FIG. 4.—RUN-OFF FOR VARIOUS RAINFALL

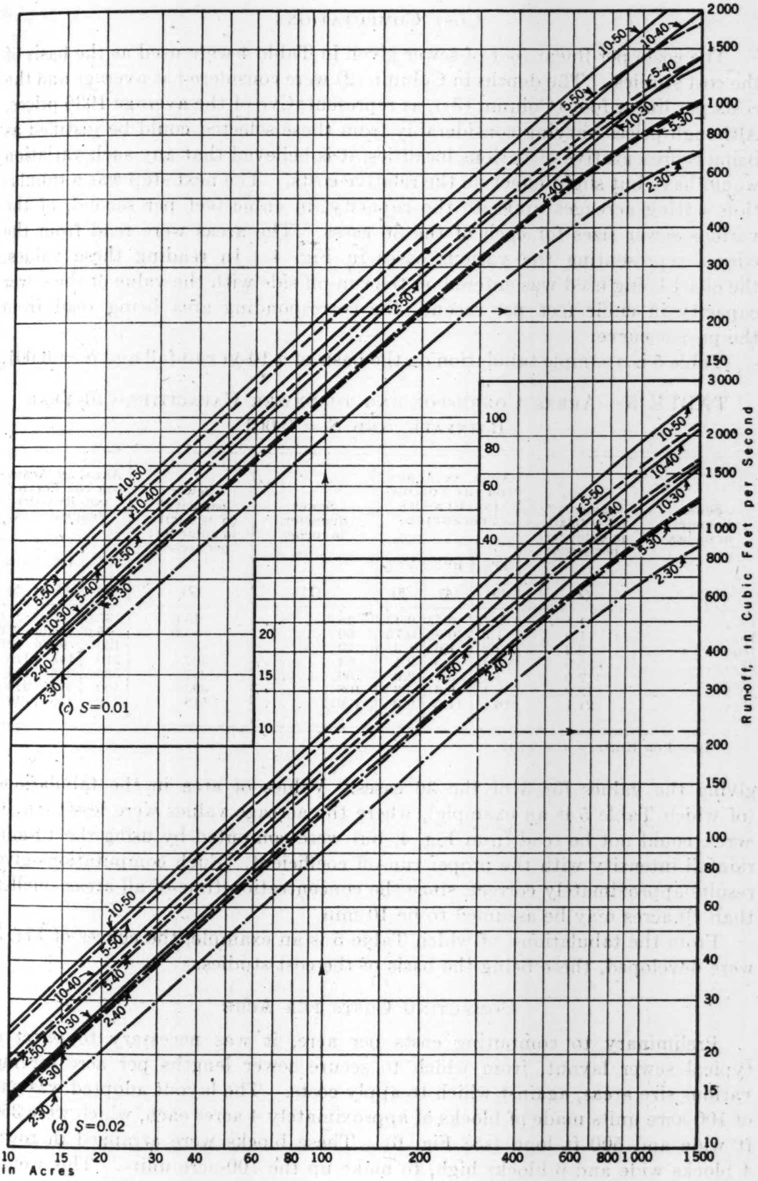

Curves and Run-Off Coefficients

Cost Computations

The costs per linear foot of sewer given in Table 4 were used as the basis of the cost studies. The depths in Column (2) were considered as average and the costs per linear foot (Column (3)), as representative of the average 1936 prices. Although prices varying considerably from those selected could be justified as being representative of various localities, it is believed that any such variation would have but slight effect on the relative costs. The next step was a tabulation setting acreages opposite the capacity, in cubic feet per second, of the various sewer sizes for each of the 36 cases. The areas were read from the curves representing the various cases in Fig. 4. In reading these values, the chart being used was entered on the run-off side with the value of the sewer capacity in cubic feet per second, the corresponding area being read from the proper curve.

Table 5 is a sample tabulation on the basis of a 10-yr rainfall and $S = 0.001$, giving the values for 3 of the 36 cases. Values of area in the tabulations (of which Table 5 is an example), where the acreage values were less than 10 acres, could not be read from Fig. 4, but were computed by using the 10-min rainfall intensity with the proper run-off coefficient. Such computations give results approximately correct, since the concentration time of all areas smaller than 10 acres may be assumed to be 10 min.

TABLE 5.—AREAS CORRESPONDING TO SEWER CAPACITIES—10-YEAR RAINFALL; AND $S = 0.001$

* Based on Kutter's $n = 0.013$.

From the tabulations, of which Table 5 is an example, the curves of Fig. 5 were developed, these being the basis of the cost studies.

Computing Costs per Acre

Preliminary to computing costs per acre, it was necessary to select a typical sewer layout, from which to secure sewer lengths per acre serving various size areas, against which to apply costs. The layout adopted was one of 100-acre units made of blocks of approximately 4 acres each, which were 350 ft wide and 500 ft long (see Fig. 6). These blocks were arranged in rows, 4 blocks wide and 6 blocks high, to make up the 100-acre units. This would actually be about 96 acres, but was taken as 100 acres to simplify computa-

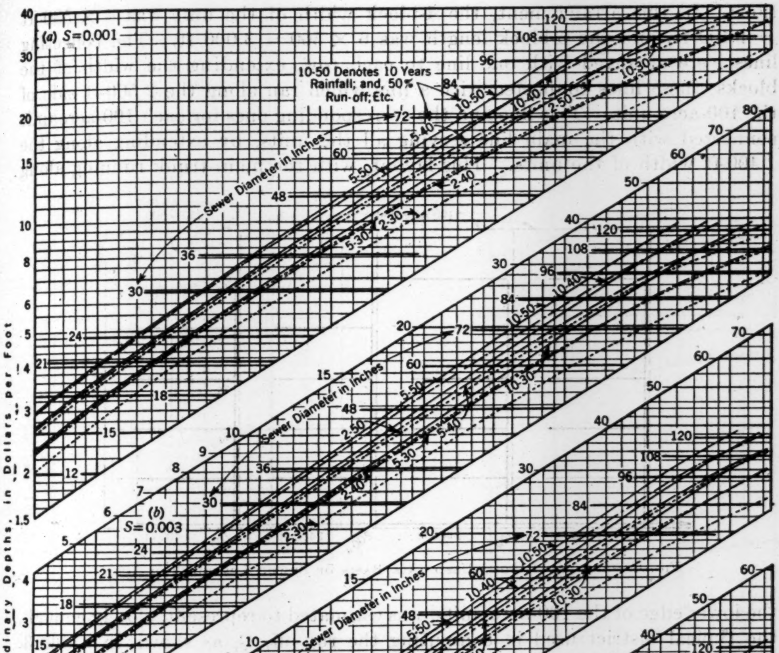

FIG. 5.—COST AND SIZE CURVES FOR TWO-YEAR, FIVE-YEAR, AND TEN-YEAR RAINFALL FREQUENCIES AND RUN-OFF COEFFICIENTS OF 0.30, 0.40, AND 0.50

tions. In this arrangement, the 4-block width of the unit was 4 × 530 ft = 1 400 ft, and the 5-block length was 6 × 500 = 3 000 ft. The collecting lines were arranged with one line to each row, extending the width of the blocks; these lines connected with a line which ran along the 2 500-ft side of the 100-acre unit. This line and the corresponding ones for each 100-acre unit connected with the main line serving all the units, by extending along the 1 400-ft width of the units. This layout, with the main trunk running along the lower edge of the 100-acre units, was estimated to represent, closely enough, the typical district used in computing the run-off, Q, as shown in Table 3. The arrangement in blocks and units made it possible to compute costs per acre for the various cases with a minimum of labor. Table 6(a) gives the computed lengths of sewer per acre for various areas served, and accumulated sewer lengths per acre. Using the sewer lengths per acre given in Table 6(a) and costs per foot taken from Fig. 5, the costs per acre were computed. Table 6(b) is an example of the computations for one of the 36 cases.

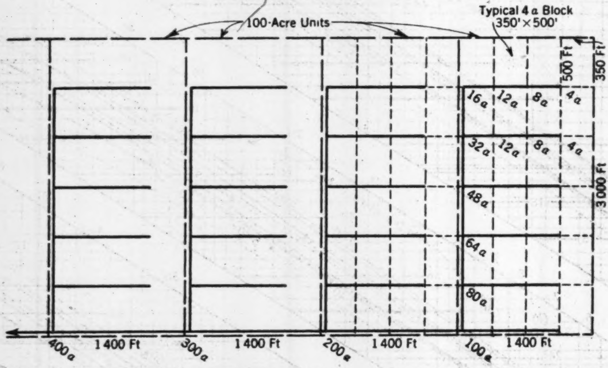

FIG. 6.—ASSUMED LAYOUT USED AS A BASIS OF SEWER LENGTHS PER ACRE

Using the results of the cost computations, curves representing costs per acre for 32 of the 36 cases were plotted on Fig. 7. The studies of cost per acre do not give values for areas smaller than 100 acres, as the purposes of the study are amply served without dealing with smaller areas.

The principal purpose of computing costs per acre, as given by Fig. 7, was to relate or compare costs of the various cases. Although the lengths per acre used may vary considerably from those for an ordinary problem, they are so proportioned for the various areas that the relative costs are fairly representative of the ordinary problem. To compare results in any ordinary problem with the results of this study, merely determine the accumulated sewer lengths per acre as in Table 6(a), and proportion the results to a comparative basis.

Note that in connection with computing costs per acre, the use of the interpolated costs per foot as taken from Fig. 5 was necessary to eliminate the 5% to 10% variation or error that would result from using the cost per foot of the sewer size which came nearest to serving the area in question.

* Actual cost, Column (2) × Column (4). † No increase in accumulated sewer lengths per acre for areas greater than 100 acres, for a layout on which sewer lengths are based (see Fig. 6). ‡ For 10-yr rainfall, 30% run-off, and 0.003 slope.

EFFECT OF VARIOUS FACTORS ON COST

Using the costs per acre from curves in Fig. 7, an analysis of relative costs was made and plotted in the form of curves in Fig. 8. The relative costs for each factor were determined by using various combinations of the other three factors and then running through the range of values of the factor under consideration with each combination. In the cases of slope and run-off coefficient, it was found that relative costs for the factor under consideration did not vary materially with the various combinations of the three other factors. Hence, the cost relations for each of these factors are represented by one curve.

In the cases of the rainfall and area factors, it was found that there was some variation of cost relation due to different combinations of the other three factors, and limiting curves were necessary to represent the cost relations for these factors. In the case of the rainfall frequency relations, the upper limiting curve is shown for slopes of 0.01 and 0.02 (steep slopes) and an area of 100 acres (small area), whereas the lower curve is for slopes of 0.001 and 0.003 (flat slopes) and an area of 1 000 acres (large area). The analysis revealed that only slight difference was due to variation of run-off coefficients. The difference due to variation of area from 100 acres to 1 000 acres was found to be about the same as that due to variation of slopes from 0.02 to 0.001. Hence, these factors should be taken into consideration in using the chart to estimate decrease or increase in cost due to the use of a lower or higher rainfall frequency. For example, for a 2-yr frequency, a slope of 0.002, and a 500-

acre area, the value would be found slightly above the lower curve; or, the cost for a 2-yr frequency would be about 80% of the cost for a 10-yr frequency.

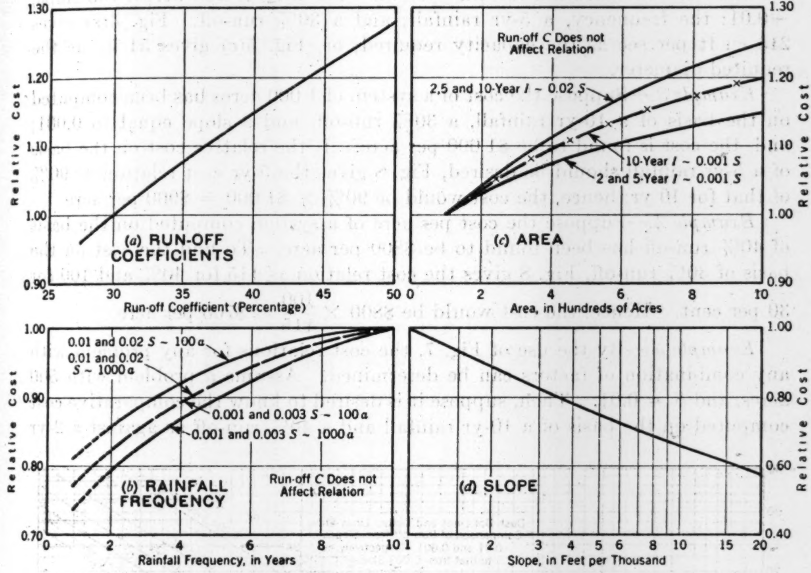

FIG. 8.—RELATIVE EFFECT OF VARIOUS FACTORS ON COST

In the case of area and slope factors, the cost relation curves are of no practical use other than as a matter of general interest because there would be a variation of these factors only in separate problems; for example, in the case of slope, if in a certain problem the slopes were 0.01 instead of 0.001, the cost relation would be 64%, or 36% less. In the case of area on the basis of a 10-yr rainfall and a 0.001 slope, the cost relation for 1 000 acres would be 120% of that for 100 acres, or 20% more.

EXAMPLES

To illustrate the practical use of the results of this or similar studies, a number of examples are given.

Example 1.—Assume a 10-yr rainfall, a 30% run-off, and a slope of 0.003. The design of a main trunk in accordance with these data is indicated in the following tabulation:

Areas to be served, in acres	Read run-off, in cubic feet per second, from Fig. 4(b)	Read diameter, in inches, from Fig. 5(b)
20	27	33
50	62	42
100	118	54
200	220	72
400	405	90

Example 2.—Assume the case of an area, for which it is desired to determine the capacity required, or the size of a main trunk outlet, without computing the time of concentration for the system. The area is 200 acres; the slope, −0.01; the frequency, a 5-yr rainfall; and a 30% run-off. Fig. 4(*c*) gives 215 cu ft per sec as the capacity required; or, Fig. 5(*c*) gives 54 in. as the required diameter.

Example 3.—Suppose the cost of a system of 1 000 acres has been computed on the basis of a 10-yr rainfall, a 30% run-off, and a slope equal to 0.001; and, the cost is found to be $1 000 per acre. If the relative cost on the basis of a 5-yr rainfall should be desired, Fig. 8 gives the 5-yr cost relation as 90% of that for 10 yr; hence, the cost would be 90% × $1 000 = $900 per acre.

Example 4.—Suppose the cost per acre of a system computed on the basis of 40% run-off has been found to be $800 per acre. To find the cost on the basis of 30% run-off, Fig. 8 gives the cost relation as 115 for 40% and 100 for 30 per cent. Hence, the cost would be $\$800 \times \frac{100}{115} = \$700$ per acre.

Example 5.—By the use of Fig. 7, the cost relations for any problem with any combination of factors can be determined. Assume a problem with 500 acres, and $S = 0.01$. Then, suppose it is desired to know the comparative cost computed on the basis of a 10-yr rainfall and a 40% run-off as against a 2-yr rainfall and a 30% run-off. From the 0.01-curve in Fig. 7, for 500 acres (10-yr rainfall, and 40% run-off), the cost per acre is $810. From the 0.01-curve in Fig. 7 for 500 acres (2-yr rainfall, and 30% run-off), the cost per acre

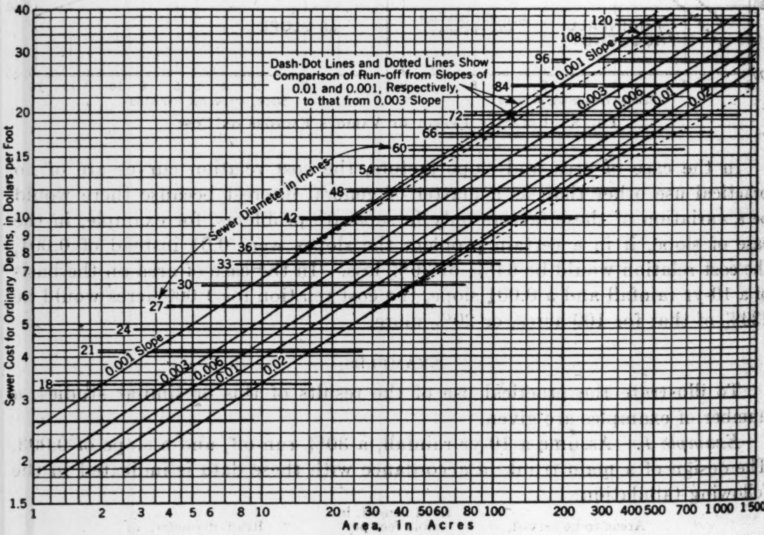

FIG. 9.—DESIGN CHART FOR STORM SEWERS; BASED ON TEN-YEAR RAINFALL; 30 PER CENT RUN-OFF; $S = 0.003$; AND KUTTER'S $n = 0.013$

is \$600. Hence, if a problem had been solved on the basis of a 10-yr rainfall, and a 40% run-off and if the cost had been found to be \$800 per acre, the cost on the basis of a 2-yr rainfall and a 30% run-off would be $\$800 \times \frac{600}{810} = 800 \times 74\% = \$595$ per acre. This example should make clear that the use of the costs per acre in Fig. 7 is as an index of cost for comparative purposes and not for direct answers, in cost per acre, for a particular problem.

DESIGN CHART

As a result of this study, the writer has developed a chart (Fig. 9) for use in storm-sewer design which has proved to be a valuable aid in preliminary design and in checking designs. The sample-design problem in Table 7 is solved by the customary method and the diameters required are found to be identical with those determined by Fig. 9.

OBSERVED EFFECTS OF GEOMETRIC DISTORTION IN HYDRAULIC MODELS

By Kenneth D. Nichols,[1] Jun. Am. Soc. C. E.

With Discussion by Messrs. Herbert W. Ehrgott, E. H. Taylor, Herbert D. Vogel, and Kenneth D. Nichols.

Synopsis

Geometric distortion in hydraulic models is a systematic change from geometric similitude involving the use of exaggerated depths or slopes. In many cases the advantages of distorted models more than compensate for their disadvantages; hence distorted models are commonly used in many countries. Questions of costs and benefits, size of prototype, laboratory facilities, time, and requirements of turbulent flow and adequate tractive force in the model may make geometric distortion necessary or desirable in hydraulic laboratory models. For both technical and economic reasons the degree of geometric distortion is usually greater for large than for small prototypes.

In this paper, studies of specific models are summarized and analyzed for effects of geometric distortion in the behavior of the models. Comparative data are presented for an undistorted and a distorted model of the same prototype showing effects of slope distortion and depth distortion upon velocity conversion factors, from model to prototype. Data are presented for other models showing effects on bed formations of variations in bed materials (including light-weight materials), and slope and depth distortions. Selected studies of flood control and river navigation in the Mississippi River System are summarized and analyzed. Brief reference is also made to observations, pertinent to effects of geometric distortion, in many other hydraulic studies.

Analysis of the data showed that a lesser degree of distortion may be required in movable bed models if light-weight materials are used to simulate the stream bed. The analysis also outlined representative methods of compensating for distortion and effecting hydraulic similarity in specific details when over-all similarity cannot be expected.

Note.—Published in June, 1938, *Proceedings*.

On the basis of this study recommendations are made concerning the use, design, and operation of distorted models.

INTRODUCTION

Definition of Geometric Distortion.—Geometric distortion in hydraulic models is a systematic change from geometric similitude involving the use of exaggerated depths or slopes.

The general term, "geometric distortion," should be sub-divided into "depth distortion" and "slope distortion." In depth-distorted models the depth scale, $d_r = \frac{d_m}{d_p}$, is greater than the length or horizontal scale, $L_r = \frac{L_m}{L_p}$. The degree of depth distortion, $b = \frac{d_r}{L_r}$, is the ratio of the depth scale to the length scale. The degree of slope distortion is the slope scale, $S_r = \frac{S_m}{S_p}$. In slope-distorted models the slope scale is other than unity, and S_r may be greater than or less than b. Depth distortion and slope distortion may be used independently, or in combination. In practice, depth distortion is usually accompanied by slope distortion of equal or greater degree. Other types of geometric distortion have been proposed, but their use is not common enough to warrant further discussion.

Advantages and Disadvantages of Distorted Models.—The advantages of distorted models may be listed as follows:

(1) In order to satisfy the minimum requirements of tractive force, turbulent flow, or measurable depths for a model of any prototype, a larger horizontal scale is necessary if the model is undistorted than if distorted. (Comparisons between a distorted model and an undistorted model apply also to models with a high degree of distortion and with a low degree, respectively.) The distorted model will have the following advantages over the undistorted model: (*a*) It will occupy a smaller space; (*b*) less water will be needed; (*c*) the laboratory facilities and personnel required will be less; (*d*) a shorter time may be required for the model study; and (*e*) the cost of the model study will undoubtedly be less.

(2) For very large prototypes the cost of the smallest practical undistorted model may be prohibitive, whereas a smaller distorted model of lesser cost may be economically justifiable and may serve the desired purpose.

The disadvantages and limitations of distorted models are:

(1) A smaller distorted model usually will depart from true similarity in more details of model performance than the smallest practical undistorted model of the same prototype;

(2) Owing to the lack of all-around similarity, a distorted model must be designed to obtain hydraulic similarity in specified details; hence, it cannot be used for all-around studies;

(3) A distorted model usually needs more extensive field data for verification purposes than an undistorted model; and.

(4) Because of the uncertainty of many of the effects of distortion the dangers of a model study being a failure are greater for a distorted model than for an undistorted model.

Degree of Geometric Distortion Used in Practice.—For any prototype the questions of costs and benefits, size of prototype, laboratory facilities, time, and requirements of turbulent flow and adequate tractive force in the model may make geometric distortion necessary or desirable. These factors combined with certain natural characteristics of rivers usually require a greater degree of distortion for large prototypes than for small prototypes. This is borne out in experience as follows: Considering chiefly costs and benefits, in practice the length scale used in hydraulic models decreases as the size of the prototype increases. For example, in hydraulic laboratories in Prague and Zurich one finds a length scale of 1 : 50 used and suitable for the small rivers in Czecho-Slovakia and Switzerland; at Karlsruhe Laboratory, in Germany, a scale of 1 : 170 or 1 : 200 for a Middle Rhine River model; at Berlin, Germany, 1 : 200 for a Middle Elbe River model and 1 : 500 for a Lower Elbe River model; at Budapest, Hungary, 1 : 500 for the Danube River; and at Vicksburg, Miss., 1 : 450 to 1 : 2 000 for the Mississippi River.

Due mainly to technical reasons and to a change in the characteristics of rivers with size, the depth scale for these models does not fluctuate over such a wide range. In the model a certain minimum depth and slope are usually necessary to insure turbulent flow, measurable depths, or sufficient tractive force. Moreover, for most rivers, as the size of the river increases, the slope and the grain size of the bed material decrease, and the ratio of width to depth increases. Consequently, for larger prototypes the depth scale must be proportionately greater than the length scale.

In the foregoing models, the range in depth scales was only 1 : 50 to 1 : 200, compared to a range in length scales of 1 : 50 to 1 : 2 000. The range in depth distortion was from 1 to 20, and the range in slope distortion was from 1 to 26. Models of the larger prototypes were built with the greater degree of geometric distortion.

DESIGN OF DISTORTED MODELS

Design of River Models.—The design of a geometrically distorted model, like most engineering design, involves the careful balancing of many conflicting factors, and requires much sound judgment if the finished product is to be useful. The procedure in hydraulic model studies is as follows:

I. Preliminary Work.—

(*A*) Study all aspects of the field problem and determine those phases for which model tests may be of value. Consider the limitations of distorted models. Decide on the general type, scope, and purpose of the model study.

(*B*) Secure and assemble all necessary field data. Special data may be necessary for the verification of a distorted model.

II. Design of Models.—

(*A*) Tentatively, select the extent of model area, and the horizontal and vertical scale ratios. If a movable bed model is considered, also tentatively select the bed material.

(*B*) Modify this tentative design on the basis of: Laboratory facilities available (particularly the water supply and space available); turbulent flow requirements; the limits of accuracy of measurements; roughness requirements to obtain the desired velocity scale (for movable bed models substitute tractive force requirements to move bed material); the probable effects of geometric distortion; and a comparison of the costs of the model with the value of benefits to be derived from the model.

(*C*) Prepare adequate plans for the verification and operation of the model. In the preparation of these plans particular attention must be given to the probable effects of distortion.

(*D*) Complete the design of the model.

III. Construction of Model.—

(*A*) Use construction methods that will permit subsequent necessary alterations to be made. In movable bed distorted models it may be desirable to modify the degree of distortion after the model is built.

IV. Operation of Model.—

(*A*) Conduct adjustment and verification tests. Additional field data may be necessary to complete the verification tests. Special observations should be made to determine the effects of geometric distortion.

(*B*) Conduct formal model tests pertaining to the field problem. For these tests the model should be operated in accordance with special operating conditions determined during the verification tests. During all the tests make observations to determine the effects of geometric distortion, particularly the effects on the comparative powers of the model.

V. Report.—

(*A*) Report and interpret the model test data and observations. The interpretation of the effects of distortion on model results is of major importance.

Other Fundamental Principles.—In every step of the foregoing outline the importance of the effects of geometric distortion is emphasized. Evidently, the design of a distorted model cannot be outlined independent of the necessary preliminary work and subsequent construction, operation, and report. The designer of a distorted model must consider all phases of the study during the design phase; particularly, he must anticipate the effects of distortion in the subsequent verification and operation of the model and in the interpretation of the test data.

In addition to the foregoing procedure the following four fundamental principles of distorted model design and operation are presented:

(1) Field data must be available for a model verification, and definite plans must be made for this verification. The model operator must assure himself by appropriate comparisons of model and prototype behavior that the model faithfully simulates the prototype in the particular details being studied.

(2) A distorted model should be designed for a particular problem. A given model can only be used to solve problems closely related to the one for which it was designed. If the study involves several different problems, two or more models or a larger model may be necessary.

(3) The effects of scale, and of depth and slope distortion, should be analyzed carefully in conjunction with the fundamental laws of hydraulics in order to avoid costly mistakes in the construction and operation of the model, and the interpretation of model results. In considering these effects it should be remembered that the primary aim of most distorted models is to effect hydraulic similarity in specific details when over-all similarity cannot be expected.

(4) Light-weight bed materials may be used in movable bed models in order to reduce the degree of geometric distortion necessary.

It is evident that a knowledge of the effects of geometric distortion is of major importance in the design, operation, and interpretation, of distorted models. Because most knowledge concerning the effects of distortion is obtained from specific model studies, the experience of the laboratory personnel must be considered in model design in some such way as are the laboratory facilities. The experience of the designer undoubtedly influences his design.

Abstracts of Model Studies

Fourteen hydraulic studies pertaining to the observed effects of geometric distortion are summarized in Table 1 and further described in the following text. Items Nos. 4 and 13 refer to studies in Berlin, Germany (Preussische Versuchsanstalt für Wasserbau und Schiffbau); Item No. 7 was from the University of Manchester, Manchester, England; and the remainder were tests made at the United States Waterway Experiment Station, at Vicksburg, Miss., Item No. 14 being in part from Cornell University, at Ithaca, N. Y. Items Nos. 4, 7, 10, 11, and 13 had sand beds; Item No. 12 had a light-weight material for the bed; Item No. 14 had both fixed and sand beds; and the remainder were all fixed beds.

Item No. 1, Table 1.—Tests of the St. Clair River sills were conducted in a tilting flume, supplementary flume tests being conducted in conjunction with the model study to determine the back-water effect of submerged sills (21) (33).[2] The conclusions reached were: (1) The back-water produced by any given sill varies as the square of the velocity of approach; (2) tests conducted with equal Froude's number gave approximately similar results regardless of scale; (3) the shape of the sill, particularly that of the up-stream face, influences the back-water produced by the sill, the back-water being greater for a vertical face than for a sloping face; and, (4) for the large spacings proposed, the effect of one sill is not reduced by the addition of more sills.

Items Nos. 2 and 3, Table 1.—Models were constructed of a 3-mile stretch of the St. Clair River (just below Lake St. Clair) to determine the back-water effects of a series of submerged sills (21) (33). The relation between depth scale and length scale for the distorted model is expressed by:

---

[2] Numbers in parentheses refer to the Bibliography in the Appendix.

$$d_r = L_r^{0.75} \text{.......................} (1)$$

In the distorted model the sills were built to an undistorted scale of 1 : 30. It was impossible to roughen the bed surface sufficiently to obtain the required

* Numbers in parentheses refer to corresponding items in Appendix. † Width of flume = 6.6 ft. †ᵃ Width of flume = 2.0 ft. ‡ d_m = 0.16 ft. § d_m = 0.49 ft. ‖ d_m = 0.25 ft to 0.58 ft. ¶ Variable. ** Varies. †† S_m = 1 : 800. ‡‡ S_m = 1 : 150. §§ S_m = 1 : 400. ‖‖ S_m = 1 : 1 200. ¶¶ Velocity varied from 0.47 ft per sec to 0.99 ft per sec.

Froudian Velocity Scale, the relation between the velocity scale and the depth scale being:

$$v_r = 1.15\, d_r^{0.5} \text{.......................} (2a)$$

instead of,

$$v_r = d_r^{0.5} \text{.......................} (2b)$$

This shows that the so-called Law of Compatibility, based on equal roughness coefficient in model and prototype (that is, when d_r is expressed by Equation (1) the velocity scale is expressed by Equation (2*b*)), is of little practical value.

The undistorted model, operated in accordance with Equation (2*b*) indicated less back-water than the distorted model. When operated in accordance with Equation (2*a*), two conclusions were indicated:

(*a*) Sills with vertical faces, or with slopes of 1 on 1, indicated approximately the same back-water as the distorted model, thus supporting the contention that when velocity and roughness requirements can be satisfied a model with a low degree of distortion may be used for this type of problem; and,

(*b*) Sills with faces sloped at 1 on 3 indicated about twice as much back-water as the distorted model. For these latter tests, in the distorted model, the toes of the sills were almost touching and the sills no longer retained their individual action; hence, the back-water was reduced.

Conclusion (*a*) confirms the belief that, in a depth-distorted model, an overfall structure should be built undistorted to the depth scale; but Conclusion (*b*) illustrates that there are limits to the application of this rule.

Item No. 4, Table 1.—Supplementary flume tests were made in the Prussian Experiment Institute for Hydraulic Engineering and Ship Building, in Berlin, Germany, for a model study of the Elbe River (27) (43). These tests were made to determine the relative effects of depth and slope distortion, and the effect of change in cross-section of an impermeable training dike on the scour resulting from the dike. In the first tests, the flume was considered to be a depth-distorted model; but the cross-sections of the dikes were built to various scales $\left(L_r = \frac{1}{40};\ d_r = \frac{1}{40};\ L_r = \frac{1}{60};\ d_r = \frac{1}{40};\ L_r = \frac{1}{80};\ d_r = \frac{1}{40};\ \text{etc.} \right)$, representing depth distortions, b, of 1, 1.5, 2, 3, 4, 5 and ∞.

Two findings pertaining to geometric distortion were:

(1) The change in cross-section of a dike such as would be caused by depth distortion will increase the resulting scour around the dike. The change in slope of the dike from the shore end to the outer end such as caused by depth distortion will also increase the relative scour. The tests did not indicate that the increase of scour would be in the correct ratio to the increase in depth scale; and,

(2) An increase in slope distortion will increase the scour resulting from a dike.

Item No. 5, Table 1.—The purpose of the so-called "Coney Island Model Study" was to find a method of eliminating the back-lash eddy along the lock approach below Dam No. 36 in the Ohio River (21) (44). Similarly, to Items Nos. 2 and 3, the relation between the depth scale and the length scale is expressed by Equation (1). In the model, the dam was built to an undistorted scale of 1 : 60. Two findings are pertinent:

(1) As in Items Nos. 2 and 3 it was determined that sufficient roughness could not be applied in order to reduce the velocity scale to that of the Froudian requirement. By applying roughness, n_m was increased from 0.013 to 0.021. The resulting velocity scale was approximately 20% to 25% too great.

(2) In spite of excess velocities a good reproduction of the back-lash eddy was obtained, and the model was suited for the study.

Item No. 6, Table 1.—A model of a 600-mile stretch of the Mississippi River (see Fig. 1) was constructed in order to determine the comparative value of various flood-control measures (21) (44). The model was particularly effective in giving a vivid picture of the flood problem for the entire Lower Mississippi Valley, by the reproduction of past major floods. Considering this aspect, the model might be termed to have an educational value, which is often under-estimated when evaluating the benefits to be derived from a model study. The conclusions were:

(1) Before the application of roughness it was determined that the model discharge scale varied with stage from a value of 1.484×10^{-6} to 0.823×10^{-6}. This variation could not be tolerated because the length of the model was so great that the corresponding varying time scale introduced serious errors into the form of a flood wave.

(2) Computations for selected sections of the model revealed that the scale for hydraulic radius varied from 1 : 118 to 1 : 527.

(3) In order to obtain similarity of hydraulic capacity for all parts of the model, variable intensities of roughness were applied and a fixed discharge scale of 1 : 1 500 000 resulted. This discharge scale is in excess of the Froudian scale of 1 : 2 000 000.

FIG. 1.—MODEL OF THE MISSISSIPPI RIVER FROM HELENA, ARK., TO DONALDSVILLE, MISS. (MODEL SCALES: HORIZONTAL, 1 : 2 000; AND VERTICAL, 1 : 100).

(4) In spite of extreme distortion and the resulting difficulties of adjustment, it was possible to verify the model by reproducing recent major floods accurately. The wealth of field data which are available for the Lower Mississippi River System permitted this verification.

Item No. 7, Table 1.—The purpose of this study was to test the effects of a barrage in the Severn River (12). Various sizes of sand were used in an effort to improve the verification. Three findings are to be noted:

(1) The type of sand used as a bed material influences the bed configuration. The height of banks formed in the model was found to be a function of the diameter of the sand grains.

(2) The model having a vertical scale of 1 : 200 was in closer agreement with the prototype than the model having a vertical scale of 1 : 100.

(3) In spite of extreme distortion a good verification was obtained.

Items Nos. 8 and 9, Table 1.—These studies were part of a general research program to determine the effects of geometric distortion (21) (34). They were conducted in existing models, changes in distortion being made by remolding the channel. No effort was made to adjust the roughness to obtain any particular velocity scale. The results showed that:

(1) The degree of distortion affects the distribution of velocity and, therefore, would affect the relative horizontal distribution of energy and the effective tractive force; and,

(2) There appeared to be greater discrepancy between the prototype and the model for a high degree of geometric distortion than for a low degree.

Item No. 10, Table 1.—This was a navigation study to determine methods of improving one or the other of the two channels at Fitler Bend, at Point Lookout, La. (Fig. 2 is a river survey made from September 2 to October 6, 1933). A low degree of depth distortion was considered necessary in order to test various dredging proposals. Light-weight bed materials were not being used at U. S. Waterways Experiment Station at the time of this study.

Three general conclusions may be drawn from this study (21) (44):

(1) For a slope distortion of $\frac{26.2}{1}$ the adjustment tests indicated that the resulting velocities were too high. The resulting thalweg was very definitely on the outside of the bend, whereas a survey of the prototype showed greater development of the inside channel.

(2) For a decrease in slope distortion the model verification was improved. Verification tests were run with a slope distortion of $\frac{19.0}{1}$ and $\frac{15.7}{1}$. The latter slope furnished the better verification of natural conditions. In both cases the movement of sand was decreased, but there still remained sufficient tractive force to provide adequate movement of the bed materials.

(3) These tests show that a change in slope distortion may result in changed bed configuration particularly in a change of thalweg alignment. They also indicate the importance of adequate field data for supporting verification tests.

Items Nos. 11 and 12, Table 1.—The Robinson Crusoe Island model (Item No. 11) was designed and operated for a study at, and up stream from, the City of Memphis, Tenn. (21) (44). Because the model included the Memphis Depot area an attempt was made to use this existing model for the Memphis Depot Study (Item No. 12); but it was soon determined that the existing model was not suited for the study, and a new model was designed for the latter case. Items Nos. 11 and 12 were both navigation studies for channel improvements at Memphis, Item No. 11 being up stream from Memphis, and Item No. 12 in the approach channel to the dock of the United States Engineer Office (known as Memphis Depot). Fig. 3(*a*) shows the river survey made of the Memphis Depot area in July and August, 1935. Five conclusions are offered:

FIG. 3.—MEMPHIS DEPOT MODEL STUDIES FOR CHANNEL IMPROVEMENTS

(1) The Robinson Crusoe Island model was not suited for studying the area in the vicinity of the head of President's Island. Excessive bar building occurred on the left bank, forcing the thalweg to the center of the left-hand channel; and an excessive attack on the head of President's Island resulted.

(2) The Memphis Depot model, as first constructed, was also unsatisfactory due to excessive slope distortion $\left(S_r = \frac{20.0}{1}\right)$. (See Fig. 4.)

(3) Fig. 3(*b*) shows the improvement resulting in the verification tests due to a reduction in slope distortion. The scale was reduced, successively, from $\frac{20.0}{1}$ to $\frac{12.5}{1}$. Fig. 3(*b*) is for a slope distortion of $\frac{12.5}{1}$. A comparison of Figs. 3(*b*) and 4 with Fig. 3(*a*) shows the improvement resulting in verification tests due to a reduction in slope distortions.

Other data are:

Duration of test (Test No. 13, Run 5), in hours	27.5
Slope in prototype	0.00008
Total slope in model	0.0010
Horizontal scale of model	1 : 450
Vertical scale of model	1 : 150
Actual discharge scale	1 : 317 000
Actual velocity scale	1 : 4.7
Theoretical velocity scale, v_r	1 : 12.2
Ratio: $\frac{\text{Theoretical velocity scale}}{\text{Actual velocity scale}}$	1 : 2.6
Mean grain size of bed material, in millimeters	1.040
Specific gravity of bed material	1.85

(4) For this study excellent year-by-year field surveys were available for the area involved, and a more accurate verification thereby resulted.

(5) These tests show the advantages of using a light-weight bed material in combination with moderate depth and slope distortion instead of sand in combination with greater depth and slope distortion.

Item No. 13, Table 1.—In Berlin (27), a study of two models was conducted to determine the relative merits of depth and slope distortion in a model in which the radius of curvature of the channel was 6 m (approximately 20 ft). The following were the most significant findings:

(1) Although the tractive force available in the two models was equal (tractive force expressed as the product of depth times slope), greater bed movement occurred in the model having the greater depth.

(2) Shape and alignment of sand riffles indicated that greater depth created a greater tendency for diagonal currents or helicoidal flow.

(3) The size of the sand riffles increased with the increased depth.

(4) In the two models the location of the thalweg remained approximately the same; the depths of scour varied approximately with the depth scale. The secondary channel on the inside of the bend was not so apparent in the depth distorted model. This latter is probably due to the increased movement of sand to the inside of the bend, caused by the increase of diagonal currents.

Item No. 14, Table 1.—In the bifurcated flume tests of Item No. 14, tests were conducted with a fixed bed and with a sand bed, various types of sand being tested (4) (21) (36) (44). The purpose was to study the bed-load action at the fork of a stream. One branch of the flume model was a continuation of the approach channel and the other, or side channel, made an angle 30° with the main channel. The approach and two branch channels were of equal rectangular cross-section. (See references given for other types of channels and variation in the angle between the channels.) Pertinent results of these investigations are:

(1) The tests indicated clearly that for equal distribution of flow the water entering the side channel is mainly that flowing along the bottom and one side (nearer the side channel) of the approach channel. The zone of top currents turning into the side channel usually extends over less than 50% of the top width; the zone of bottom currents entering the side channel extends over the greater percentage of the bottom width.

FIG. 4.—EFFECT OF EXCESSIVE SLOPE DISTORTION, MEMPHIS DEPOT MODEL STUDY

(2) The data show clearly that for a given depth of flow, as the velocity (or slope distortion) increases, the zone of bottom currents turning into the side channel increases in width. For example, for one velocity the zone of bottom currents entering the side channel may cover 70% of the bottom width of the approach channel, whereas for a higher velocity the zone may cover 80% or 90% of the width.

(3) For equal distribution of water flowing down the two channels, the percentage of bed load entering the side channel was greater than that entering

the straight channel. The percentage of bed load diverted increased as the velocity increased.

(4) For otherwise like conditions, it was shown that the bed material mixture influences the percentage distribution of bed load entering the two channels. As the bed material mixture becomes finer, and a greater percentage of the material moved is in suspension, the percentage entering the side channel decreases.

Analysis of Data and Observations

The foregoing observations, and the data in Table 1, together with some other observations not included, may be classified and analyzed under two major headings: (1) Effects of geometric distortion; and (2) behavior of bed materials. Under the first classification are discussed changes in form, changes in hydraulic capacity, changes in flow characteristics, secondary currents, and miscellaneous effects. Under the second classification are discussed the general behavior of bed materials, and the use of light-weight bed materials.

Changes in Form.—The most obvious effect of depth distortion is in the change in the form of the cross-section of the channel and of the structures. Change in form influences the back-water effect of structures and also, in movable bed models, varies the scour pattern caused by such structures. The ratio of width to depth in model and prototype is not the same, and the relative area of cross-section affected by side-wall influence on hydraulic flow is thereby altered. In movable-bed, depth-distorted models the side slope of the bed material is steepened, which may increase the rate of scour of the material; or, in cases where the angle of repose of the submerged material is exceeded it may result in an undesirable sloughing. Depth distortion changes the shape of the channel in the model, thereby causing the scale for the hydraulic radius to be a variable. The hydraulic capacity of the channel is thus affected. All the foregoing effects of depth distortion must be considered in model design, operation, and interpretation.

Hydraulic Capacity of Channel.—Both depth distortion and slope distortion influence the hydraulic capacity of an open channel. The hydraulic capacity of a channel is its capacity to carry water, as measured by the rate of flow through a given reach for a given stage. Based on Manning's formula for velocity the capacity of a channel in model and prototype is similar only when,

$$Q_r = \left[\frac{L\,d\,R^{0.67}\,S^{0.50}}{n}\right]_r \qquad (3)$$

in which Q_r = discharge scale = $\frac{Q_m}{Q_p}$; R_r = hydraulic radius scale = $\frac{R_m}{R_p}$; and n_r = coefficient of roughness scale = $\frac{n_m}{n_p}$.

In depth-distorted models it has been shown that R_r varies from cross-section to cross-section and also in the same cross-section for different stages; hence, if Q_r is to remain constant, n_r must vary within each cross-section and from cross-section to cross-section. It is common practice to vary n_r by roughening a model by trial and error.

In the Helena-Donaldsonville model (Item No. 6, Table 1) the roughness varied from rough stuccoed concrete to extremely smooth concrete. In fact, in a few isolated sections it was impossible to make the concrete smooth enough and the section was enlarged arbitrarily.

If the slope of the model is also distorted, the roughness must be further increased to compensate for the greater slope, or the discharge scale will increase. In many studies the actual value of the discharge scale is relatively unimportant as long as a similarity of hydraulic capacity is obtained; but in other studies it is desirable to comply with Froude's requirement for the velocity scale. (Supplementary flume tests showed that compliance with Froude's law was desirable for the St. Clair River model tests.) For a distorted model this requirement is met only when Equation (2*b*) holds. Combining Manning's formula and Froude's law, it can easily be shown that this formula applies only when,

$$\frac{R_r^{0.67}\, S_r^{0.50}}{d_r^{0.5}\, n_r} = 1 \ldots\ldots\ldots\ldots\ldots\ldots (4)$$

(The criterion (35), $v_r = d_r^{0.5}$ when $d_r = L_r^{0.75}$, is based on the assumption that $n_r = 1$, which is seldom true.)

When the degrees of depth and slope distortion are equal, it follows that greater roughness must be used as the degree of distortion increases. For such a distorted model of a rectangular channel the roughness scale should increase as the width-depth ratio of the prototype, the degree of distortion, or the horizontal scale of the model, increases (21). Consequently, the velocity scale must often exceed the value indicated by Equation (2*b*). Where this requirement must be satisfied, one must roughen the model to extremes, reduce the depth and slope distortion, or reduce the slope distortion.

Changes in Flow Characteristics.—Slope distortion and depth distortion will cause changes in the characteristics of flow. Variation of the depth or slope distortion will affect the magnitude of velocity and also the velocity distribution, such as to change the form of the vertical and horizontal velocity distribution curves. Another effect of distortion is to alter the direction of currents. Particularly, the relative divergence of surface and sub-surface currents may be changed. Distortion may cause eddies to occur in a model where none exists in the prototype; or it may affect the size, shape, location, and intensity of existing eddies or rollers. The intensity of turbulence or the pulsating character of the flow may be altered. Another common effect of distortion is an undesired increase in the transverse slope of the water surface. Many experimental data are available to show specific instances of such changes, but insufficient data are at hand to provide a basis for the formulation of definite laws concerning such changes.

Of particular interest is the effect of geometric distortion on the shape of the vertical velocity curve. Experimental data and field observations on natural streams show definitely that depth, slope, form of channel, and roughness affect the form or shape of the vertical velocity curve. For example, the following statements have been fairly well substantiated by field and laboratory observations:

(*a*) The vertical velocity curve approximates a parabola, the axis of which is horizontal and passes through the point of maximum velocity.

(*b*) As the roughness of the bottom increases, the depth of the filament of maximum velocity and that of mean velocity in any vertical, is less. The ratio of surface to bottom velocities also increases.

(*c*) For the range of model slopes and model depths commonly used in hydraulic laboratories, a change in slope or depth distortion will result in a change in the vertical velocity distribution. The exact nature of the law of variation has not yet been determined conclusively.

(*d*) Side-wall effect on the vertical velocity curve is apparent to a point about 2.5 times the depth from a side wall.

(*e*) A rapidly rising channel bottom—that is, a bottom of adverse slope—tends to make the velocity distribution more uniform, whereas a rapidly falling bottom tends to make the ratio of upper to bottom velocities increase.

Hence, a change in the combination of depth and slope distortion will change the vertical velocity curve in some unpredictable manner. The change in distribution of velocity becomes of particular importance when a bend section or divided flow around an island or obstruction is considered.

Secondary Currents.—When water flows in an open channel secondary currents usually exist. From the standpoint of hydraulic models the most important of these are the cross-currents near the bottom of a stream, which are set up in a channel whenever there is a change in direction of flow such as that caused by a curved channel, a divided channel, a large obstruction, deflecting dikes, etc.

One explanation for the cross-currents is as follows: Usually in an open channel the surface currents are moving faster than the bottom currents. Hence, when a change in direction occurs, it takes less force to change the direction of the bottom, than the surface, currents. At a bend in the channel a transverse slope is set up due to the change in direction. This slope acts as an unbalanced force on each filament of current and deflects it so that the radius of curvature of each filament is approximately proportional to the square of its velocity. In a bend section the radius of curvature is generally less for the bottom than for the top currents and this phenomenon is a part of helicoidal flow.

In general, such cross-currents exist for any change of direction. For example, in Item No. 14, Table 1, the bulk of the water entering the side channel was that water which had been flowing near the bottom of the approach channel. In these tests the horizontal angle between the direction of the top and bottom currents varied from zero to 180 degrees.

In movable bed studies the engineer is particularly interested in the direction of the bottom currents because they are the principal determining factor in the direction and amount of movement of the bed.

Inasmuch as geometric distortion affects the magnitude of velocity and also the form of the vertical velocity curve, it is logical to assume that the nature of the cross-currents will also be influenced. Items Nos. 10, 12, 13, and 14, in Table 1, and other studies, illustrate, directly or indirectly, the effect of a change in distortion on the secondary currents.

Analysis of these studies indicates that usually greater depth or slope distortion will increase the divergence of surface and bottom currents, and that the divergence is more marked for an increase in depth distortion than for an equal increase in slope distortion. Other factors, such as horizontal velocity distribution, relation between wave velocity and mean velocity, roughness, effect of one bend on a lower bend, etc., greatly affect the nature of flow. Additional data are needed before conclusive relationships can be established.

Miscellaneous Effects.—In addition to the specific examples referred to in Table 1, countless other examples of discrepancies introduced by geometric distortion could be presented. Many of these discrepancies are unimportant or may be properly weighed in interpreting model results. Among the more important, especially in movable bed models, are the following effects which have been observed at the U. S. Waterways Experiment Station (in all cases the name of one representative model or reach of a Mississippi River model is given in parentheses, see Fig. 1 for the geographic location of many of these studies):

I. Excessive Scour:
  - (*A*) At a bend (Hotchkiss Bend);
  - (*B*) At the end of deflecting dikes (Island 35);
  - (*C*) At the head of sand-bars, tow-heads, and islands (Cat Island);
  - (*D*) At relatively narrow sections (American Cut-Off); and,
  - (*E*) At a point of junction of two streams (Vice-President's Island).

II. Improper Location of Scour:
  - (*A*) At a bend (Head of Passes); and,
  - (*B*) Displacement down stream below a sill or submerged dike (Head of Passes).

III. Unstable Side Slopes:
  - (*A*) Steep bank occurring in prototype (Memphis);
  - (*B*) Dredging holes or cuts (Cat Island); and,
  - (*C*) Sand dikes (Rifle Point).

IV. Other Effects:
  - (*A*) Excessive bar building at a relatively wide section (Waterproof Cut-Off);
  - (*B*) Displacement down stream and relative straightening of crossing (Cow Island);
  - (*C*) Introduction of eddy and a resultant bar at a point of sudden widening of the channel (Cottonwood Bar);
  - (*D*) Improper thalweg alignment and sand deposits in a bend (Cat Island);
  - (*E*) Improper division of flow and excessive development of one channel and excessive deterioration of the other in cases of divided flow around an island (Harklerodes Island).

Behavior of Bed Materials.—In most model studies the movement of the bed material is by rolling or sliding along the bottom; hence, the movement of material and the resulting bed configuration is largely influenced by the bottom currents. Inasmuch as the direction of bottom currents is influenced by distortion, the bed configuration will also be affected.

A change in the bed material may change the bed configuration. This is illustrated in the Severn Estuary model (Item No. 7, Table 1). An explanation is as follows: A change in the grain size or the specific weight of the bed material will affect the rate of movement and may affect the type of movement (that is, movement by riffles to movement by banks, or true bed-load movement to movement in suspension, etc.). Any change in the nature of movement will increase or decrease the roughness, which, in turn, will affect the magnitude of velocity and the cross-currents. Hence, the bed configuration may be changed by merely substituting one bed material for another. One may take advantage of this factor during the verification of a model. If one bed material will not provide a successful verification, a change of bed material may materially improve the verification.

Light-Weight Bed Materials.—For a given hydraulic model study, the degree of geometric distortion necessary may be reduced by the use of light-weight bed materials instead of natural sand (see Fig. 5 and Table 2). Many laboratories have resorted to the use of such materials. In Europe, broken briquettes of coal, pumice, and amber are being used successfully. The U. S. Waterways Experiment Station has operated models with haydite, coal, and gilsonite and the use of (I) limed rosin has been considered.

TABLE 2.—CHARACTERISTICS OF MODEL BED MATERIAL, CURVES IN FIG. 5

22.....	Fitler sand..................................	2.65	0.485	0.0010

Light-weight materials have the advantage over heavier materials in that, for a given grain-size, movement occurs at a lower tractive force and that coarser light-weight materials may be used instead of heavier sand to reduce riffling and the degree of distortion. However, the apparent specific gravity

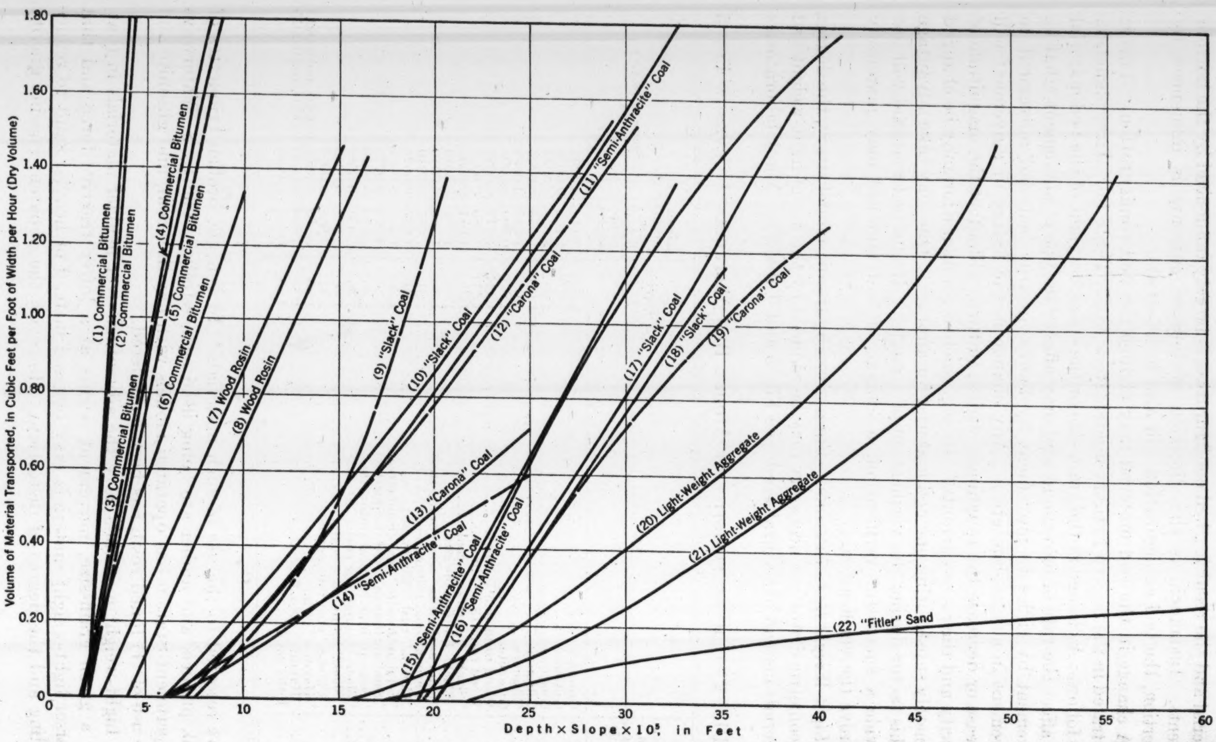

FIG. 5.—RESULTS OF FLUME TESTS ON LIGHT-WEIGHT BED MATERIALS

and size of coal, pumice, and haydite grains change after continued use. Amber and gilsonite are very costly and are extremely difficult to use. Because of their light weight these materials are not suitable for studying wave action on beaches or certain types of river problems where bars are exposed. Unless gilsonite is soaked in water, shaped rapidly to conform to the model bed, and flooded almost immediately, tiny air bubbles attach themselves to the grains and cause the material to float. However, the use of light-weight materials is feasible, and it is recommended as a substitute for extreme geometric distortion. Experience indicates that a combination of moderate depth distortion, moderate slope distortion, and light-weight bed material is better than the use of one extreme to the exclusion of the others.

CONCLUSIONS

Summary.—This study shows the following: (*a*) There is a definite need for constructing geometrically distorted models, particularly because such models are often suitable when a geometrically similar model is out of the question on account of cost or other considerations; (*b*) geometrically distorted models should be used with extreme caution; (*c*) arbitrary measures may sometimes be taken to compensate for some of the effects of distortion; (*d*) light-weight bed materials may be used to reduce the degree of distortion necessary; (*e*) in general, a change in the degree of depth or slope distortion, or in the bed material, may result in a change in model results; and finally (*f*) owing to the complex nature of many of the effects of distortion the importance of model verification cannot be over-emphasized.

Recommendations.—On the basis of this study the following recommendations are made: (1) Geometrically distorted river models should be avoided whenever suitable undistorted models can be constructed at reasonable cost; (2) distorted models should be designed for specific purposes and they should not be used for general studies; (3) the designer should weigh, intelligently, the probable effects of distortion in order to avoid failures or reconstruction costs; he should consider carefully the advisability of using light-weight bed materials instead of extreme depth or slope distortion; and (4) the operator should assure himself by appropriate comparisons of model and prototype behavior that the model faithfully simulates the prototype in the particular details being studied.

ACKNOWLEDGMENTS

The writer wishes to express his thanks to the Institute of International Education for a fellowship to study this subject in Germany; to Professor H. Seifert, Director, Preussische Versuchsanstalt für Wasserbau und Schiffbau, Berlin, Germany, for offering valuable suggestions and for making available data from that laboratory; to the Directors, past and present, and the Staff, of the U. S. Waterways Experiment Station, Vicksburg, Miss., for advice and assistance; and to F. T. Mavis, M. Am. Soc. C. E., Head of the Department of Mechanics and Hydraulics, State University of Iowa, Iowa City, Iowa, under whose direction this study was completed.[3]

---

[3] The paper is based on data contained in "The Observed Effects of Geometric Distortion in Hydraulic Models," a thesis presented by the writer to the State University of Iowa in 1937, in partial fulfillment of the requirement for the degree of Doctor of Philosophy.

DISCUSSION

HERBERT W. EHRGOTT,[4] **ESQ.** (by letter).—The general attitude toward models expressed in this paper may be described as an optimistic skepticism, a wise attitude for all hydraulic experimenters to adopt. When working for a "crank," it is politic to make a close study of his foibles, and to discover the limits beyond which it is not safe to go. No one will question the statement that hydraulic models—particularly open-channel models—are "cranky." The author has undertaken to evaluate the queer quirks of distorted models, while persuading them to yield valuable information despite their shortcomings.

In his discussion of Studies Nos. 2, 3, and 5, Table 1, Lieutenant Nichols shows that the so-called Law of Compatibility is of little value in cases of submerged dikes in open-channel models. This conclusion is correct, and is understandable, when it is considered that the law of compatibility (Equation (1)) was derived for the case in which: (*a*) Model and prototype roughnesses are equal ($n_r = 1$); (*b*) ratio of hydraulic radii is equal to depth ratio ($R_r = d_r$); and, (*c*) there is no supplementary slope $\left(S_r = \frac{d_r}{L_r}\right)$. Of these three assumptions only the third is true in the three studies cited. The hydraulic radius ratio in distorted models is never equal to the depth ratio, and varies from section to section and from stage to stage within each cross-section. The hydraulic roughness ratio in open-channel models can seldom be made equal to unity, as is apparent from Table 3 in which are given all roughness coefficient data for small channels, available to the writer.

Referring to Item No. 15, Table 3, the gravelly earth had the following composition:

Type	Percentage
Arable earth	50
Sand	30
Fine gravel (3 to 10 mm)	10
Gravel (10 to 30 mm)	10
Total	100

In Item No. 20, the value of *n* decreases with increasing grain size, but not in direct proportion; for example:

Mean grain diameter, D_g, in millimeters	Roughness coefficient, n
0.205	0.026
0.35	0.021
0.56	0.013

The writer is inclined to be skeptical of the value of any quantitative results to be obtained in model studies of open-channel models involving submerged works, in which the channel is distorted, while the submerged sills, dikes, or

dams remain undistorted. Such problems involve both Froude's and Reynolds' Laws of Similarity, acting together in undetermined ratios (Eisner's "Zusammenwirkungsgrenz"). Only a geometrically similar model of this type may be counted upon to give results that are transferable to Nature. This is not to say that model studies such as Study No. 3, Table 1, are without value. Quite the contrary. The action of different types of submerged works, as compared with each other, may be revealed clearly by such a study; and a general knowledge of the effects of a moderate degree of vertical distortion indicates that such relative action will probably be closely similar to the corresponding action in the prototype. It is to be hoped that if and when the sills are built in the St. Clair River, a re-check will be made on models to answer the question of transferability of results in problems of this ambiguous type.

In connection with Study No. 6, Table 1, the writer has made a study of the variation of the hydraulic radius ratio from cross-section to cross-section and from stage to stage. Forty typical river cross-sections were plotted to various distortions, and the ratios of hydraulic radii for each section and for each distortion were calculated. It was found that:

(1) The hydraulic radius distortion varies approximately parabolically with the depth distortion;

(2) The hydraulic radius distortion varies with the ratio, $\frac{\text{Width}}{\text{Maximum depth}}$; and,

(3) The width-maximum depth ratio varies with stage, in a quite uniform manner, regardless of exact shape of cross-section.

There was some indication that shape of cross-section had some importance, but the indications were so slight and erratic that it was felt that inclusion of this factor would constitute an unjustifiable refinement.

The author gives a corrected "law of compatibility," into which none of the three assumptions made in the case of Equation (1) enters. This formula (Equation (4)) may be clarified, and its application simplified, if it is rewritten:

$$\left(\frac{d_r}{L_r}\right)\frac{1}{S_r\,L_r^{0.33}} = \left(\frac{R_r}{L_r}\right)^{1.33}\frac{1}{n^2} \qquad (5)$$

In this form the three adopted scales built, or to be built, into the model appear on the left-hand side, whereas the resulting discrepancy from dynamic similarity, due to differing hydraulic radius distortions for each stage and cross-section, are given on the right-hand side, together with the degree of roughness distortion to correct for the discrepancy. Equation (4) written in this form (see Equation (5)) makes it perfectly clear why adjustment of a fixed bed model, such as the Helena-Donaldsonville Model (Study No. 6, Table 1), involves "cut-and-try" variation of the roughness throughout the model, and at various stages. Theoretically, the exact roughness to be applied for each section and each stage could be computed from Equation (5) (assuming that Manning's equation is strictly applicable to the model, which it is not); actually, it is simpler to apply approximately the correct average roughness and then smooth or roughen the model locally to "iron out" the numerous humps and sags. Equation (4) would seem to indicate that, within the limits imposed by: (*a*) The streaming-shooting limit; (*b*) the laminar-turbulent limit; (*c*) the hydraulic roughness limit (n_m cannot be made smaller than 0.009, nor greater than 0.026, without actually constricting the cross-section); (*d*) the limit imposed by the angle of repose of bed material; and, (*e*) bed movement limit (tractive force limit); any combination of vertical, slope, and hydraulic roughness distortions which makes the left-hand member equal to unity, may be used.

Since the depth distortion, once chosen, is usually invariable, and since the hydraulic radius distortion for any particular section and stage is fully determined by the shape of the cross-section and the vertical distortion, it follows that if Froude's law is to be approximated, a model with constant roughness (at different stages) must be operated with varying slope distortion. Conversely, if a model is to be operated with constant slope-ratio, the roughness ratio must be made to vary with stage so as to keep Equation (4) in balance.

In practice, of course, these considerations impose difficulties, often insuperable, so that the model cannot be brought to operate in compliance with Froude's law. The usual practice is to operate with constant roughness and slope ratio, and a discharge scale which varies with stage. (One model study completed at the United States Waterways Experiment Station, in 1938, was made with a variable slope scale, with excellent results.)

In Conclusion (3) of his description of the Helena-Donaldsonville model, Lieutenant Nichols gives the discharge scale, and states that it is greater than that required by Froude's law. If the reference is to Equation (3) it should be explained that this is not Froude's law, but an equation of compatibility between Froude's law and Manning's formula; Froude's law proper does not apply to open-channel models. If a different formula for C were used, which is applicable equally to both model and prototype, it is possible that the discharge scale would be found to check closely with that required by theory. By plotting the value of Chezy's C for a large number of observations taken from models of all sizes and descriptions, as well as from small, medium, and large canals, flumes, and rivers, against the corresponding values of the product, $V\,R$, the writer has developed the formula,

$$C = \frac{1.81}{n^{0.9375}} (V\,R)^{0.1175} \qquad \text{(6a)}$$

or,

$$V = \frac{1.96\, R^{0.700}\, S^{0.567}}{n^{1.062}} \qquad \text{(6b)}$$

which appears to fit models as well as prototypes. It would be interesting if the author would compute the value of Q_r for the Helena-Donaldsonville model, using Equation (6b) for comparison with the empirically determined value of $\frac{1}{1\,500\,000}$.

Under Study No. 13, Table 1, the author cites a case in which the same model was tested with two different depths, to determine the effect of distortion in a sharp bend. His first conclusion is that although the tractive force available in the two models was equal, greater bed movement occurred at the greater depth (smaller slope). This is extremely interesting as indicating that a true criterion of tractive force should include the factor of depth to a greater degree than in DuBoys' law—a conclusion which the writer has reached independently by a study of the tractive force investigations of the U. S. Waterways Experiment Station. The tractive force, according to DuBoys' law, is expressed by the product, $\rho\, d_x\, S$; in which d_x is the depth of flow at the particular point in question, and S is the general water-surface slope of the stream, the resultant of all the dynamic forces acting throughout the stream in that vicinity. DuBoys' expression for tractive force does not consider velocities, except as they are tied to d_x (through R), and S. Bed velocity is generally acknowledged to be of first importance in the transportation of bed materials, but practical means of measuring bed velocities have not been developed. Since they are determined by the velocity distribution, and the hydraulic resistance to flow near the boundaries, it would seem that a true criterion of tractive force should be intimately linked with Chezy's formula for mean velocity. A preliminary analysis of the flume traction studies at the Waterways Experiment Station shows that an equation of the general form:

$$G = \frac{K\,C^3}{\rho_o}\,(d\,S - d_0\,S_0)^{1.5} \qquad (7)$$

adequately represents the relationship between the solid flow and fluid flow in a small, straight, rectangular channel with smooth sides. In Equation (7): G is the solid flow, in cubic feet per foot width of flume per hour; K is an empirical constant representing the effect of shape and size of bed material, and coefficient of friction between the material and the bed (includes the factors, g and ρ_1); C is the Chezy roughness coefficient; ρ_o is the (wetted) specific gravity of the bed material; $d\,S$ is the depth-slope product for the particular hydraulic conditions under consideration; and, $d_0\,S_0$ is the corresponding product for conditions obtaining at inception of "general" movement.

It will be noted that according to Equation (7) the quantity of material moved will increase as the cube of the friction coefficient. If Manning's formula for C is used, $G \approx \frac{R^{0.5}}{n^3}$. The result is the same as that observed in the results of the author's Study No. 13, Table 1. Of course, the results of flume traction studies cannot be applied directly to natural open-channel models, or to full-sized streams; but it is to be expected that as knowledge of the mechanics of bed-load movement expands, some formula of the general form of Equation (7) will be found to apply. The author's observations on the effects of distortion on velocity distribution are very pertinent. It is here that the crux of the entire question of evaluation of distortion effects is to be found. The vertical velocity curves and the corresponding isovel plots are the resultant of all the complex dynamic effects of sinuosity of channel, variation in size and shape of cross-section, absolute roughness, type and quantity of bed-load movement, etc. If a relationship could be established between the isovel plot, the bottom velocities, and Chezy's friction coefficient, C, one may anticipate a rational design of open-channel models. Herein lies a fruitful field of investigation.

The writer would like to plead with all engineers who may have occasion to make stream measurements, to make every effort to report at the same time all pertinent information as to: (*a*) Water temperatures; (*b*) rate of change of surface slopes; (*c*) configuration of the reach, both longitudinal and lateral; (*d*) variation in shape and size of cross-section along the stream axis; (*e*) mean grain size of bed material, or careful description of channel roughness; (*f*) type of bed-material movement (smooth, riffling, sand waves, super-wave smooth, anti-dune), together with average height, wave length, and speed of sand waves; (*g*) quantity of bed load; and, (*h*) kineticity of flow (this requires taking two velocity cross-sections and the slope between them). The accumulation of a widely distributed body of such data should lead to a much more useful table of *n*-values, and eventually to a definitive solution of the entire problem of open-channel flow.

Study No. 7, Table 1, is one of the most interesting model studies reported to date. Professors A. H. Gibson and J. Allen (see author's bibliography reference (12))[5] made an exhaustive study of the suitability of various bed materials for this particular model, which involved open-channel flow (unidirectional), tidal flow in a funnel-shaped estuary, and tidal bore. Any conclusions which they draw should be applied to other models only with the greatest caution, since the two vertical distortions used were far greater than has been generally accepted as a safe limit for vertical distortion. Despite such excessive distortions, extremely good verification was obtained, particularly as to height of sand banks and depth of pot-holes. Lieutenant Nichols stresses the importance of a careful verification; in the opinion of the writer this cannot be over-emphasized. The reliance to be placed in any results obtained with new dispositions built into the model depends entirely upon the accuracy with which the model was able to reproduce known conditions or known changes in Nature. In the study of the Severn Estuary about one-half the bed materials tested (which included sands, emeries, and pumices) failed to reproduce the correct position of the thalweg just below a sharp bend. Some of the materials that produced good results in the $\frac{1}{200}$-model failed in this respect when used in the $\frac{1}{100}$-model; on the other hand, one sand, which gave the incorrect thalweg in the $\frac{1}{200}$-model gave the correct position in the model with smaller vertical distortion. It is evident that some undetermined relationship between the size and specific gravity of the bed material, and the tractive forces developed by the flowing water (dependent upon the vertical and slope distortions) is effective in such a model, and that a fine balance must exist between the solid and fluid flows if similarity of bed-load movement is to be attained. It is significant that for the three materials which produce the best results, the values of the product, $d_g\,(\rho_g - \rho_1)$, were nearly equal.

The author is to be congratulated upon his paper, which avoids all matters of conjecture and deals only with actually observed effects of geometric distortion. Hydraulic models are here to stay, and within the limits imposed by the particular laboratory, and funds available, distortions are unavoidable; it is a question of fundamental importance, therefore, to determine what allowances are to be made for each such distortion in the interpretation of the measured model results. The paper is a valuable contribution to current knowledge in this field, so far as vertical and slope distortions are concerned. Much remains to be written, particularly in the field of bed material distortion.

E. H. TAYLOR,[6] JUN. AM. SOC. C. E. (by letter).—The fact that geometric distortion of river models is theoretically invalid has long been recognized. Solution of the model equations for a number of effects—for example, backwater, tractive force, or transverse slope at a bend—leads to the conclusion that $L_r = d_r$, or that the distortion ratio should be unity. Tests conducted at the Hydraulic Laboratory of the University of California at Berkeley, Calif., during 1935 and 1936 support Recommendation (1) that "geometrically distorted river models should be avoided whenever suitable undistorted models can be constructed at reasonable cost."

(a) HIGH DEGREE OF TURBULENCE (b) LOW DEGREE OF TURBULENCE

FIG. 6.—ARRANGEMENT DESIGNED TO PRODUCE TURBULENCE

In an attempt to determine the effect of geometric distortion upon the bed configuration of a movable bed model, an arbitrary prototype was constructed in a channel 1 ft wide, and its model was built in another channel to a horizontal reduction scale of two. The model was constructed so that it could be operated as either a distorted or as an undistorted model. Arbitrary rates of flow were set up in the prototype so as to produce definite bed configuration about certain simple obstructions which could be easily modeled in the smaller channel. The obstructions, or baffles, about which the flow was made to pass, were built to cause either a high degree of turbulence, or to allow the flow to proceed smoothly. Shown in Fig. 6 are plan views of two of the arrangements used, in which w = channel width (either 12 in., or 6 in.).

No attempt at "verification" of the prototype bed configuration was made, but discharges and lengths of time for the model were calculated on the basis of the Froudian law of similarity. At the conclusion of each test, the elevations of the prototype and model beds were compared at a large number of corresponding points and an error curve was prepared. Fig. 7(*a*) shows the relative correspondence of the distorted and undistorted model to their prototype obtained from a typical set of runs. The agreement between models and prototypes was found to be superior for the condition represented by Fig. 6(*a*). Fig. 7(*b*) shows the relative correspondence of undistorted models of Arrangements *A* and *B* to their respective prototypes. It was concluded that:

(1) Undistorted models more truly represent their prototypes than distorted models; and,

(2) If Froude's law is used as the model criterion, models of highly turbulent systems are more faithful than models of relatively smooth flows.

The writer's understanding of "model verification" of movable bed models is as follows: A known hydrograph covering a certain period of time in Nature is simulated in the model. Several trials may have to be made, adjusting the model discharge, slope, or time, until a certain combination of hydraulic conditions is obtained whereby the model reproduces the natural bed condition. The model is then said to be adjusted, and the assumption is made that these experimentally determined hydraulic conditions fix the proper ratios for discharge, time, etc., for the particular model. The model is then assumed to be capable of indicating future changes in bed conditions which would be due, perhaps, to proposed training works.

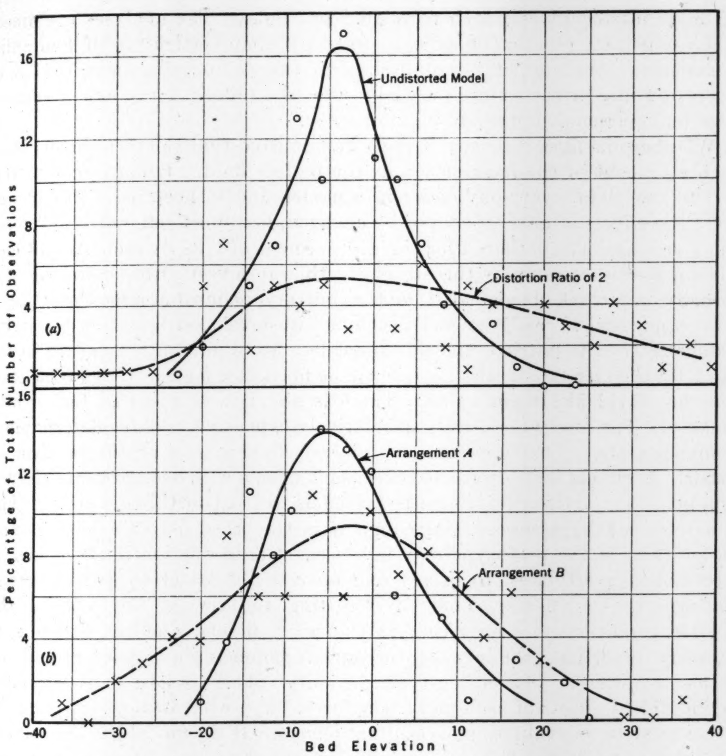

FIG. 7.—VARIATION OF BED ELEVATION AT CORRESPONDING POINTS OF MODEL AND PROTOTYPE IN PERCENTAGE OF MAXIMUM DIFFERENCE IN BED ELEVATION

It may be reasoned, however, in view of the foregoing Conclusion (2) that the degree of turbulence, or nature of the flow system, is a factor that influences the discharge or time scale necessary to produce similarity of bed configurations between a model and its prototype. Thus, the introduction or removal of groynes and dikes in the model stream would effectively alter the turbulence which would seem to invalidate the experimentally determined model ratios. The matter of movable bed model "verification" impresses the writer as being somewhat uncertain.

HERBERT D. VOGEL,[7] M. AM. SOC. C. E. (by letter).—A rising vote of thanks is due Lieut. Nichols from the harassed brotherhood of hydraulic model testers, for he has laid low their ghost of despair and given them new courage with which to meet their difficulties. Fear engendered by ignorance is dispelled by the light of knowledge; hence, there should result from his paper a bolder and more intelligent approach to related problems. The analyses contained in the paper are worthy of serious study by all investigators of hydraulic phenomena. Although it is not desired to take material issue with Lieut. Nichols on any of the points raised by him, the following random thoughts, based on experience, appear to be in order.

---

[7] Capt., Corps of Engrs., U. S. Army; Instr. The Army Engr. School, Fort Belvoir, Va.

Whether one likes it or not, it must be admitted that the ideal model is as much a figment of the imagination as the perfect fluid. Being forced at the start to use plain, every-day water in a model, and to keep it on this planet where the effects of gravity cannot be changed, one must relinquish any fond hope one may have harbored for the achievement of true dynamic similitude. It is not meant to imply by this statement that an investigator should don the eternally dark cloak of a defeatist; on the contrary, he must assume the attitude of an opportunist, ready to meet each newly developed situation squarely, anxious to try the untried, and determined to leave no stone unturned in his search for the ultimate truth. Above all, he must face facts as they are instead of as he would like them to be. There is no place in research for wishful thinking. The model is a handy, if relatively expensive, tool for determining, in advance, the probable effects of proposed changes in a prototype river or harbor. It should be expected to reveal such effects with accuracy and clarity. By a process of verification it can be tested as to trustworthiness, and, in this, all surety and hope repose. Although it is true that individual forces and accelerations of the prototype may fail of exact reproduction in the model, it is possible, nevertheless, to design and operate the latter so as to make it duplicate known effects. Thus, by "cutting and trying," by varying the variable conditions, by adjusting as the need directs, and by resorting to necessary distortions, the investigator can overcome dissimilarities engendered by the use of water and a garden-type of gravity. Perhaps he cannot determine the individual effects of each and every force, but—what is more important—he can come to an evaluation of resultant effects. If the model has been tested faithfully as to its capability to reproduce past occurrences, there is no reason to suppose that it will fail to predict the future with an equal degree of accuracy.

In general, allowing for differences in materials comprising beds and banks, every alluvial river may be considered as a rough model of every other. Traction in each must be sufficient to move the bed materials down stream; otherwise, there would be no river. If depths are less in the smaller rivers, slopes must be correspondingly greater; and, similarly, unless slopes are greatly exaggerated there must be definite increases in relative depths. Of course, there are definite limits to the slopes that may be obtained. Consider, briefly, the Elbe River, in Germany, as compared to the Lower Mississippi River, slopes of the former being greater on an average of from 25 to 70 per cent. If one may look upon the former as an approximate model of the latter, one should expect to find an exaggeration of the vertical scale. The horizontal scale, based on bankful measurements, is about 1 : 7; the vertical scale, similarly considered, is about 1 : 4. This indicates that a vertical exaggeration of about 1.75 has been applied by Nature herself.

Referring to Lieut. Nichols' statement that models of the Elbe River have been built to horizontal scales of 1 : 200 and 1 : 500, these values would correspond to scales of 1 : 1 400 and 1 : 3 500 for the Mississippi River. The vertical scale of the larger Elbe model (1 : 40) produced an exaggeration, in depths, of 5. Considering that Nature had already applied an exaggeration of 1.75, the total exaggeration was 5 × 1.75, or 8.75. For a model of the Mississippi River, with a horizontal scale of 1 : 1 400, this would permit the selection of a vertical scale as large as 1 : 160, approximately. In the Elbe model, slopes were exaggerated by the factor, 8, in order to produce movement of the bed; but because of the warping that results therefrom in over-bank areas, this is no longer judged the best practice. Without supplementary slope to produce bed movement, it is probable that a vertical exaggeration of about 7 would have been necessary. This fact, translated to Mississippi River terms, would justify an exaggeration of more than 12, all of which tends to show that greater distortion may be tolerated in models of large, rather than in those of small, rivers. Extending the theory to small mountain streams, one can see that little or no distortion would be in order. It is fortunate, of course, that for such streams it is not needed, whereas the reverse is true for large rivers.

It is doubtful if any one should, or could, establish an ultimate permissible limit of distortion. Lieut. Nichols has wisely refrained from so doing, although he has indicated discrepancies that have been observed in models greatly exaggerated as to depths and slopes. The entire problem resolves itself eventually into a question of money. If information is desired relative to the effects of proposed improvements in a certain reach of river and the facts are not obtainable by analytical methods, a model test is the obvious means available. The question of how much to spend is then pertinent. Certainly no test should be undertaken that will cost more than it can be hoped to save. Having determined the maximum expenditure permissible, it then remains to select suitable scale values. The horizontal scale is determined largely on a basis of costs; the vertical scale on a basis of depths that will be needed in the model. Distortion (or vertical exaggeration) is the result, and if an arbitrary limit is imposed, it may be that a model study will be precluded. If no worthy results are possible it would be better, of course, to abandon plans for a model then and there; but in almost every case some beneficial data may be expected. It is then necessary to weigh the estimated value of anticipated results against the cost thereof, in dollars and cents, and to arrive at a final decision on that basis.

A word of warning should be added in closing as an addition to the recommendations of Lieut. Nichols, all of which are concurred in. Models of spillways and similar structures should be made geometrically similar, in every respect, to prototypes. Distortion of any kind applied thereto results in a change of basic shape, and so alters frictional coefficients that direct comparisons are impossible. In an open-channel model, frictional differences are adjusted by the process of verification previously referred to, but in the case of spillway models it frequently happens that the prototype exists only in drawings or in imagination; hence, no check is possible. Since the heights of such structures are usually great with respect to length sand widths, there is little temptation, if any, to exaggerate vertical dimensions. In case of an excessive length of crest, a sectional model will generally suffice.

KENNETH D. NICHOLS,[8] JUN. AM. SOC. C. E. (by letter).—The frank criticism and constructive comments in the discussions are appreciated. The writer is in practically complete agreement with the views expressed by Captain Ehrgott, and his discussion aids materially in clarifying the original paper. He presents some interesting and valuable data on the observed values of *n* in small models. The observation and gradual collection of more of such data will greatly facilitate the work of the model designer in the future.

Captain Ehrgott implies that Equation (4) might be applicable in the design of movable bed models. In the writer's opinion Equations (3) and (4) have little application in the average movable-bed model study. They are intended primarily for consideration in design and operation of fixed-bed models used for hydraulic studies. In the average movable-bed model of a river the bed-movement considerations are so much more important than certain hydraulic requirements that the latter must be subordinated. Only in certain types of river tidal models do hydraulic and bed-movement requirements necessitate equal consideration. In general the purpose of the model should be kept firmly in mind and the study confined to rather narrow limits. This limitation has brought about the necessity for having different techniques for fixed-bed models and for movable-bed models.

The writer is in complete agreement that Equation (3) is not Froude's law, but an equation of compatibility between Froude's law and Manning's formula. Conclusion (3) of Item No. 6 is a comparison of the empirically determined discharge scale with the "so-called" Froudian discharge scale as determined by the application of Equation (2*b*)—not Equation (3).

Captain Ehrgott's remarks on Item No. 7 are particularly appreciated. The additional evidence of the variable results obtained by changing bed materials cannot be repeated too often nor over-emphasized. Complete and careful verification of each and every model is an absolute requirement of sound model technique.

Mr. Taylor's discussion gives the impression that he has accepted a defeatist attitude concerning the use of distorted models. The writer is in agreement that within certain ranges "undistorted models more truly represent their prototypes then distorted models," but as stated in the original paper, for a large prototype very frequently the smallest practical undistorted model is economically unjustifiable from the standpoint of cost whereas a smaller, but yet practical, distorted model may be of definite value and also a good investment economically. A distorted model is not a perfect tool, but it may be better than no tool.

Mr. Taylor's skepticism of verification as being somewhat uncertain is justifiable to a certain extent. Verification may be uncertain and when carelessly and improperly done, it may lead to placing faith in an absolutely untrustworthy model. However, the large number of successful model studies has shown that, in the hands of experienced personnel, a distorted model, properly verified, is of definite value for aiding in the solution of difficult hydraulic problems.

---

[8] Lieut., Corps of Engrs., U. S. Army; Instr., Dept. of Civ. and Military Eng., U. S. Military Academy, West Point, N. Y.

Captain Vogel has presented an excellent discussion of some of the common-sense principles that govern the conception and use of hydraulic models. It is well occasionally to rise above the petty arguments, pro and con, concerning the exact accuracy of hydraulic models and to view the problem as a whole to decide whether or not the results have been of benefit. Moreover, the importance that Captain Vogel attributes to economic considerations cannot be over-emphasized. Practical considerations and experience should outweigh minor theoretical arguments that the tool is imperfect.

BEAM CONSTANTS FOR CONTINUOUS TRUSSES AND BEAMS

By George L. Epps,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. C. W. Deans, George W. Lamb, A. A. Eremin, Leo Legens, and George L. Epps.

Synopsis

The material presented in this paper deals with the determination of the elastic constants used in various methods of analyzing continuous beams and trusses. By rotating the ends of the beam in turn and computing the elastic curve, the constants are determined for a span. This method simplifies greatly the process of determining stresses in continuous trusses and girders.

Introduction

The method of determining beam constants by elastic weights, described herein, was first developed for use in the analysis of continuous beams of variable moment of inertia and, later, was extended to include continuous trusses. Since the application of this method to continuous trusses is more involved, it will be explained in detail. The simpler application to continuous beams will be indicated afterward.

The usual method of analyzing continuous trusses is to assume various reactions as redundants and compute the elastic curves with loads in their places. In Fig. 1(*a*), Curve *A E F D* is the deflection curve for a unit load at Point *B*; Curve *A G F D* is the deflection curve for a load of sufficient magnitude at Point *C* to produce a deflection at that point equal to *C F*; and the

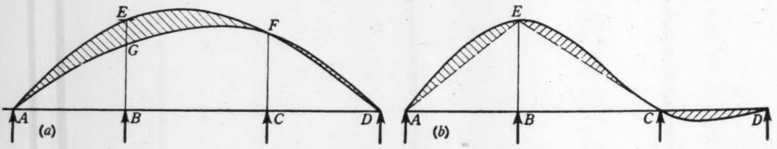

Fig. 1

Note.—Published in October, 1938, *Proceedings*.

[1] Senior Engr., Design Dept., State Highway Comm., Topeka, Kans.

shaded area between these two curves represents the ordinates of the required influence line to some scale. These deflections are several times larger than the influence ordinates that are obtained from them and, therefore, must be determined quite exactly if the ordinates are to be accurate.

A very clear illustration of the necessity for great exactness is given in an example of a 3-span continuous girder analyzed by Mr. V. L. Pierce[2] in 1935. In Fig. 2 the deflections at the pier, R_2, for the loads shown are 4.2666 and -3.2666, and the influence ordinate is the difference, or 1.0000. The larger of these deflections is more than four times the required ordinate and must be accurate to 0.025% if the ordinate is to check within 0.1 per cent. In a 5-span continuous girder, analyzed in the Design Department of the Kansas Highway Commission, the larger deflections were thirty-three times the ordinate, thus requiring very precise calculations to obtain the correct value of the influence ordinate. Thus, it will be seen that the deflection (and hence, the necessary precision of calculations) is increased in proportion to the fourth power of the number of spans.

FIG. 2.—DETERMINATION OF INFLUENCE LINES FOR THE REACTIONS OF A CONTINUOUS BEAM

The method explained herein makes possible the application of moment distribution, slope deflection, conjugate points, and similar methods, to the analysis of continuous trusses. Using these methods the moments are determined at each pier. From these pier moments the changes in reactions due to continuity are found. These changes in reactions are indicated by the shaded areas of Fig. 1(*b*). The dashed line of this diagram is the influence line for R_B if there is no continuity at the piers, and the solid line or curve becomes the influence line for R_B of a 3-span continuous beam. The part of the influence ordinate between the dashed and solid lines is not more than one-third the total ordinate, and, consequently, an error of 0.3% in this part will reduce to 0.1%, or less, of the total. Inasmuch as slide-rule computations can easily be made to an accuracy of 0.3%, this method readily lends itself to the use of the slide-rule. The first time the method was applied by the writer to a continuous truss (a 5-span bridge) the influence lines for moments, shears, and reactions at each pier were obtained in one week less than the customary office time. The reaction lines thus found, checked within 0.1% with those computed by other designers who were using the method of redundant reactions. The method of redundant reactions required two weeks to find the influence lines for reactions only.

---

[2] "Simplified Solution of Influence Lines for the Reactions of Continuous Beams," by V. L. Pierce, *Civil Engineering*, December, 1935, p. 798.

In the analysis of a continuous truss or girder by slope-deflection or moment distribution methods, the stiffness, carry-over factor, and influence line for fixed-end moments are required for each end of each span. All these quantities may be obtained by the use of elastic weights. According to Müller-Breslau's principle, if a unit rotation is applied to the end of a beam, the opposite end being freely supported, the deflections produced will be the ordinates of the influence line for fixed-end moment. The moment required to produce this rotation is defined by Hardy Cross,[3] M. Am. Soc. C. E., as the stiffness of the beam. The rotation at the far end of the beam is the carry-over factor for moments from the far end to the near end of the beam. The foregoing constants may be used directly in the slope-deflection equations and, with proper adjustment, for the case in which both ends are fixed, in the moment distribution method. All calculations are made using elastic weights as described by D. B. Steinman,[4] M. Am. Soc. C. E., or by Hale Sutherland and Harry L. Bowman, Members, Am. Soc. C. E.[5]

THEORY

Consider the second span of a 5-span continuous truss bridge with members that are symmetrical as to length, but not as to cross-section, so that the elastic constants and fixed-end moments are different for the two ends. Two sets of computations are required. However, those for only one end will be shown herein.

Fig. 3 shows the truss span diagrammatically, the lengths of the members, their moment centers, and the external forces used in the calculations. These forces are assumed and may have any values consistent with the theory of statics. As will be seen, the left end is subjected to a moment and the right

These elastic weights are applied to a simple or conjugate beam as shown in Fig. 4. In Table 2, the first operation is the determination of the left reaction of the elastic weights by taking moments at the right end of the span. Beginning with the left reaction the shears are computed between load points. These shears are the slopes at successive points of the elastic curve of the truss under this loading.

FIG. 4

As indicated previously the end rotation or slope must be unity to obtain the beam constants. Consequently, the first column of elastic shears (Column (5), Table 2) is divided by the end slope of 362.84 to obtain the second column of elastic shears (Column (6), Table 2). From these, the moments (Column (7), Table 2) in the conjugate beam are found by summation. These moments must be multiplied by the panel length to obtain the correct value of the fixed-end moments (Column (8), Table 2). The carry-over is the last shear in Table

2 (Column (6)), or the slope of the far end of the beam, 0.509. The stiffness is $\frac{600 \times 15}{362.84} = 24.79$.

The foregoing values may be used directly in the slope deflection equations when they are written in the following general form:

$$M_{AB} = \frac{1}{1 - r_{AB}\, r_{BA}} \{E\, K_A\, [\theta_A + r_{AB}\, \theta_B - (r_{AB} + 1)\, R] + H_{AB} - r_{BA}\, H_{BA}\} \ldots\ldots\ldots\ldots (1a)$$

and,

$$M_{BA} = \frac{1}{1 - r_{AB}\, r_{BA}} \{E\, K_B\, [\theta_B + r_{BA}\, \theta_A - (r_{BA} + 1)\, R] - H_{BA} + r_{AB}\, H_{AB}\} \ldots\ldots\ldots\ldots (1b)$$

(The general formulas shown for the slope-deflection equations were developed from equations presented by Earle Russell, in "Analysis of Continuous Frames." His equations apply to constants for beams fixed at both ends; whereas, in this method, the constants are developed for one end fixed and the other free. Also, the letters designating the various terms have been changed to agree with those used in *Bulletin 108*, Engineering Experiment Station, University of Illinois.)

In using moment distribution,[6] the constants for stiffness and fixed-end moments must be calculated with both ends fixed for the intermediate spans.

---

[6] "Analysis of Continuous Frames by Distributing Fixed-End Moments" by Hardy Cross, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

The stiffness obtained previously must be divided by $1 - r_{AB}\, r_{BA}$. The fixed-end moments, C_A and C_B, are determined by combining the values for H_A and H_B according to the following equations:

$$C_A = \frac{H_A - r_{BA}\, H_B}{1 - r_{AB}\, r_{BA}} \qquad \text{(2a)}$$

and,

$$C_B = \frac{H_B - r_{AB}\, H_A}{1 - r_{AB}\, r_{BA}} \qquad \text{(2b)}$$

For those who prefer to use graphic methods, it might be shown that all the stresses for Table 1 and the computations of Table 2 may be done graphically by methods found in any text on graphic statics. It should be noted that the elastic loads must be divided by the end reaction to obtain the slope of unity at the rotated end. In using the method of conjugate points,[7] the values of u, v, p, q, s, and t are necessary: $u\, l$ is the distance from the left end of the span to the center of gravity of the elastic loads with a unit rotation at the left end; $v\, l$ is a similar distance for the right end; $\frac{p\, l}{I}$ is the sum of the elastic weights for the left end, rotated; and $\frac{q\, l}{I}$ is a similar quantity for the right end. The values of s and t are found by the construction shown in Fig. 5.

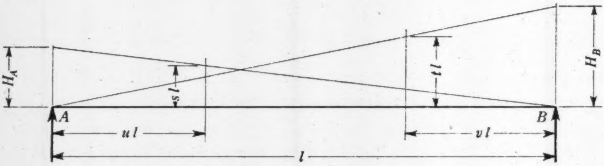

FIG. 5

In some cases it is desired to know the effect of the web system on the stresses in the truss. This can be done easily by omitting the elastic weights for the web members and carrying through the computations in Table 2.

The application of this method to beams of variable moment of inertia differs from the foregoing procedure only in the method of obtaining the elastic weights. The beam is divided into a number of sections, which need not be equal in length (although, if they are, the computations are simplified). Twelve equal sections will produce sufficiently accurate results. A moment is applied to one end of the span with the other end unrestrained and the value of $\frac{M\, dx}{I}$ is computed for each section. These values of $\frac{M\, dx}{I}$ are applied as elastic weights to the conjugate beam, as in Fig. 4. The method proceeds from this point in the same manner as explained previously.

---

CONCLUSIONS

Multiple-span, continuous truss or girder bridges may be analyzed by the method herein presented in much less time and with less work than is required by the method of redundant reactions. This method makes possible the use of slide-rule computations for continuous bridges, whereas the method of redundant reactions necessitates the use of a calculating machine.

DISCUSSION

C. W. Deans,[8] Esq. (by letter).—The writer favors the use of elastic weights for the determination of deflections of trusses, arches, and beams of variable section and finds Mr. Epps' paper most instructive and essentially useful for design office calculations.

While checking over the theory and detailed calculations of Mr. Epps' presentation it was felt that an actual demonstration of the proof of the theory by Maxwell's General Law of Reciprocal Energy Components might be helpful to those who desire to fix these ideas firmly in mind. In this law, if two states of stress for a structure are considered, the sum of the products of the forces for the first state (P_1) and the displacements, at corresponding points for the second state (y_2), is equal to the sum of the products of the forces of the second state (P_2) and the corresponding displacements for the first state (y_1). Written in equation form this is:

$$\Sigma (P_1 \, y_2) = \Sigma (P_2 \, y_1) \ldots\ldots\ldots\ldots\ldots\ldots (3)$$

Beam $A \, B$, Fig. 6, is influenced by two states of stress and Equation (3) is written for the active forces only:

$$(- F_{AB}) (\theta_A = + 1) + (P = 1) \, y = M_{AB} (\theta_A = 0) \ldots\ldots\ldots (4)$$

Therefore, $y = F_{AB}$, which demonstrates that the deflections of a beam with unit rotation at one end are the influence ordinates for the fixed-end moment at the rotated end. In Fig. 7, Beam $A \, B$ is again shown under two states of stress. From Equation (3):

$$M_{AB} (\theta_A = 0) = m_{AB} (0_A = + 1) + m_{BA} (- \theta_B) \ldots\ldots\ldots (5)$$

Therefore, $\theta_B = \frac{m_{AB}}{m_{BA}} = r_{BA}$, which demonstrates that the rotation at the far end of a beam is the carry-over factor (r_{BA}) for moments from the far end to the near end of the beam.

A practice problem illustrating the applications of Mr. Epps' method to a beam of variable section is afforded by a beam analyzed[9] previously by G. E. Large, Assoc. M. Am. Soc. C. E. The preliminary calculations are already made by Professor Large and the remainder necessary to arrive at the influence ordinates for fixed-end moments are quickly obtainable. This essential practice will help one to follow more readily the computations required for the truss analyzed by Mr. Epps.

The writer has favored the use of the column analogy,[10] or the elastic center method for the determination of beam constants; and thus he set to work to apply a moment, $M_0 = 1\,000$ ft-lb, to each end of Fig. 3 as shown in Fig. 8(*a*); thus: $\Delta_{M_0=1} = \Sigma \, g_0$; $\Delta_{V_0=1} = \Sigma \, (g_0 \, x_0^2)$; $M_0 = \frac{\Delta_{M_0}}{\Delta_{M_0=1}}$; and, $V_0 = \frac{\Delta_{V_0}}{\Delta_{V_0=1}}$. Referring to Fig. 8(*b*): $\Delta_{M_0} = 1$; $\Delta_{V_0} = -6.41\ p$; $M_{AB} = M_0 + \bar{x}_A\ V_0$; $M_{BA} = M_0 + \bar{x}_B\ V_0$; and $r_{AB} = \frac{M_{BA}}{M_{AB}}$. Finally, referring to Fig. 8(*c*): $\Delta_{M_0} = +1$; $\Delta_{V_0} = +5.59\ p$; $M_{BA} = M_0 + \bar{x}_B\ V_0$; $M_{AB} = M_0 + \bar{x}_A\ V_0$; and, $r_{BA} = \frac{M_{AB}}{M_{BA}}$.

Arrangements similar to Table 1 were made for $S_0 = \frac{M_0}{l}$ (in which l = the lever arm of the member), L, A, $\frac{L}{A}$, r, $\frac{L}{A\ r}$, and the partial elastic weights, $\frac{S_0\ L}{A\ r} = g_0'$. The elastic weights ($g_0$) were determined by summing g_0' for each panel point; and, thus it was found that the elastic center was 6.41 panel lengths from the left support at Panel Point 8. The next step is to compute $\Sigma\ g_0$ and $\Sigma\ (g_0\ x_0^2)$, which is the moment of inertia of the analogous column for the column analogy, or the vertical displacement of O, of the rigid bracket, $A\ O$ (with a vertical load $V_0 = +1$ at Point 0) for the elastic center method. These values in conjunction with V_0 and M_0 in Figs. 8(*b*) and 8(*c*) give stiffness factors and carry-over factors for both ends of the truss. The value of the carry-over factor from the far end (Point 20, Fig. 3) to the near end (Point 8, Fig. 3), thus determined, was 0.51, which is almost identical with that derived by Mr. Epps.

The influence lines for fixed-end moments are found from the values of V_0 and M_0 in Figs. 8(*b*) and 8(*c*) by calculating the cumulative displacements in the same manner as Mr. Epps in Table 2, Columns (6), (7), and (8). These values of stiffness factors, carry-over factors, and fixed-end moments can be used directly in the moment distribution and the slope-deflection methods.

The foregoing illustrates the fact that the moment transfer from span to span depends primarily on the proportions of the chord members and the depth variation of the trusses. The web members come into play mostly on account of the vertical shears caused by the loads and show up in the fixed-end moment calculations. It will save time in the calculation of Table 2 for both ends of the span to tabulate the values of $\frac{L}{A\,r}$ to be used with each of the two stress conditions.

With the elastic center method the fixed-end moments for beams having the far ends hinged are determined from the following equations:

$$H_B = C_B - r_{AB}\,C_A \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6a)$$

and,

$$H_A = C_A - r_{BA}\,C_B \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6b)$$

and the stiffness must be multiplied by $1 - r_{AB}\,r_{BA}$.

The author's method is very straightforward and even though the values found must be corrected on account of the far ends being considered hinged, only two sets of calculations (as in Tables 1 and 2) must be made—one for each end. In the suggestions offered by the writer three sets must be made, one for determining the position of the elastic center and two for the influence lines for fixed-end moments at each end. A full explanation has been made in this discussion because it was felt that a complete study would help in obtaining a clearer picture of the entire problem.

Mr. Epps is to be complimented on his choice of method, which is most efficient in that it saves design office time, and on his masterly, all-inclusive presentation. It would be interesting for Mr. Epps to comment on the feasibility of using multiple-tied, trussed arches on roller supports or multiple-trussed arches on flexible, trussed towers, and on the application of his method to their analysis.

GEORGE W. LAMB,[11] ASSOC. M. AM. SOC. C. E. (by letter).—In making possible the computation of stresses in trusses by practically all the methods that are used for beams, this paper is especially commendable. Thus, it furthers the use of indeterminate structures. Although the writer does not agree that the method of analysis presented is more accurate or more convenient to use than any of several other methods, or combination of methods, the procedure recommended does have some distinct advantages on certain types of trussed structures, especially trussed frames, and similar structures that are commonly analyzed by use of moment distribution or slope deflection.

---

[11] Asst. Bridge Engr., State Highway Comm., Topeka, Kans.

In all methods of stress analysis and design, considerable value should be placed on the capability of any step in the analysis to lend itself to the calculation of other properties of the structure. In the method presented by Mr. Epps, this is true to some degree. The influence of the change in stress in the member over the pier on any other member in one span of the truss can readily be calculated. However, there are several other properties and conditions on continuous trusses that are always necessary to compute or investigate, to which the method does not adapt itself so readily. Some of the conditions and properties that this method does not handle easily are as follows: (1) Influence lines for all the members of the truss; (2) the effect of settlement of supports and the data necessary for adjustment of reactions; (3) the calculation of dead-load deflections; and (4) it is customary to camber continuous trusses by adding to, or subtracting from, the normal length of the chords and webs, the deformation caused by the stress produced by the load for which the structure is cambered. These deformations are small and are usually given on plans to the nearest $\frac{1}{16}$ in. The differences between the fabricated dimension to the nearest $\frac{1}{16}$ in. and the deformation caused by the load are small, but the total effect of these small differences on the total truss is sufficient in some cases to cause some trouble in erection closure, and the effect should be taken care of by raising or lowering the supports or by adjusting the length of some member with a high elastic constant. Therefore, in some cases it is necessary to calculate camber in the truss with the deformation in the members different from that which the loads on the truss would indicate.

The difficulty of handling the first and second conditions can be blamed directly on the method. That is, in the first condition the influence line for the member over the support is obtained easily, but in order to obtain the influence line for a member in the truss between supports, it is necessary to have influence lines for shears and moments at each support. This involves considerable work. The second condition, settlement of supports, is also rather tedious to calculate using the constants obtained, as it involves the elastic properties of all the spans in the unit.

The third and fourth conditions, the writer believes, can be handled more easily by using a different method of calculating the elastic weights and another form for tabulating them. The writer prefers to use the method of computing angle changes in obtaining the elastic weights. Table 3 shows the value of using one set of calculations for several different properties of the truss. The diagram is one panel of a continuous truss over the reaction. The elastic shear and moments are carried over from the dotted part of the truss. It will be noted that the values given in Column (6) are used for obtaining the influence-line ordinates for reactions, the dead-load deflections, and the camber ordinates. The values shown under Column (17), with small modifications, can be used in the calculation of secondary stresses for dead load. The values given in Columns (13), (14), (18), (19), (22), and (23) are relative, and are considerably larger than the true values. This was done to obtain numbers that are easier

* E = 1. † 1 kip = 1 "kilo-pound" or 1 000 lb.

to handle. To obtain the true deflection in inches, the elastic moments must be multiplied by $\frac{12 \times 1\,000 \times 20 \times 12}{144 \times 30\,000\,000} = \frac{1}{1\,500}$. The elastic weight given to Point L_8, Column (12), is obtained as follows: $-(+0.190 \times 756 - 4.51 \times 0.352 - 4.51 \times 0.352 - 1.66 \times 3.92 + 0.718 \times 0.756) = 3.14$ with due attention being paid to the sign of the stress and whether the member is a web or a chord member, the minus sign in front of the parenthesis shows that the angle at L_8 decreases under this condition of loading. The foregoing example is part of the calculation used in designing a three-span continuous truss by the method of redundant reactions; it shows a different method of tabulating values so that they can be used in calculating various properties. It is also different inasmuch as the distances to the intersection of the members do not have to be calculated, and the dimensions and stresses within the panel are sufficient to obtain the elastic weight at any point.

The accuracy of the method of redundant reactions, as presented by Mr. Pierce,[2] is questioned in this paper on the basis of the fact that in order to be accurate the large numbers must be extremely exact because of the small differences to be obtained. In the method of redundant reactions this objection to great exactness on this basis can be avoided as follows: Instead of taking the difference between two large deflections, the deflection of the structure is obtained at all points with a unit deflection at the support for which the influence line for reaction is desired. Consider, for example, a four-span continuous beam having a constant moment of inertia and having spans of 65 ft, 80 ft, 80 ft, and 65 ft. In order to obtain deflections easily, the total length of the unit is changed to a length of unity. Let $E = 1$; and $I = 1$. The beam shown in Fig. 9 is the result. To obtain the equation for the influence line for the reaction at Point (a), Fig. 9, a unit load will be placed at Point (a) and the equation for the influence line will be written

FIG. 9

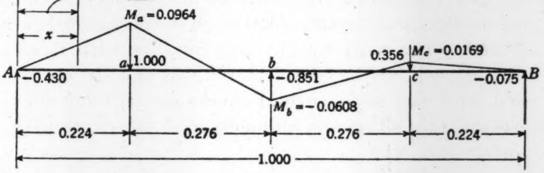

FIG. 10

Determine the reactions at Points A, b, c, and B with a unit load at Point (a). $y_{bb} = \frac{1}{48} = 0.0208$; $y_{bc} = 0.0131 = y_{ba} = y_{ab} = y_{cb}$; $y_{cc} = 0.0101$; $y_{ac} = 0.0075 = y_{ca}$; for example, y_{bc} = the deflection at b with a unit load at c, etc. Substituting:

$$0.0208\,R_b + 0.0131\,R_c + 0.0131 = 0 \quad\ldots\ldots\ldots\ldots\ldots (7a)$$

and

$$0.0131\ R_b + 0.0101\ R_c + 0.0075 = 0 \quad \text{(7b)}$$

Solving Equations (7) simultaneously: $R_b = -0.851$; $R_c = +0.356$; $R_A = -0.430$; and $R_B = -0.075$. Applying these reactions to the beam a moment diagram is obtained as shown in Fig. 10.

From elastic shear, the slopes at the supports are as follows: $\phi_A = -0.0109$; $\phi_a = -0.00012$; $\phi_b = 0.00481$; $\phi_c = -0.00124$; and $\phi_B = +0.00062$. Use these slopes and write the equation of the elastic line in Span $A-a$ as follows:

$$\frac{d^2y}{dx^2} = 0.430\ x \quad \text{(8a)}$$

$$\frac{dy}{dx} = 0.215\ x^2 - 0.0109 \quad \text{(8b)}$$

and

$$y = 0.0717\ x^3 - 0.0109\ x \quad \text{(8c)}$$

When $x = 0.224$, $y = -0.00164$.

To obtain a unit deflection at Point (*a*) and to make Equation (8*c*) apply to any four-span continuous unit with the same ratios of span lengths, multiply this equation by $-\frac{1}{0.00164}$ and substitute, letting $x = 0.224\ K$, and letting O_{A-a} = ordinate for influence line for the reaction at Point (*a*) with a load in Span $A-A$: $O_{A-a} = -\frac{1}{0.00164}(0.0717 \times \overline{0.224}^3\ K^3 - 0.0109 \times 0.224\ K)$; or

$$O_{A-a} = 1.49\ K - 0.49\ K^3 \quad \text{(9)}$$

and the area under this curve for uniform load equals 0.622. Using the foregoing reactions and slopes, the equation for the reaction at Point (*a*) with the load anywhere in the unit can be found; and a considerable portion of the foregoing information can be used in obtaining the influence lines for the other reactions. These calculations can be made with a slide-rule to the accuracy required for designing any structure. When applied generally, the foregoing procedure can be used for finding the influence line for reaction on trusses and beams of varying moments of inertia. Although it appears rather cumbersome this general method, when used by any one familiar with it, is as accurate and requires as little work for the complete analysis of a structure as any other that may be used, and also offers several checks on arithmetical errors. The complete analysis includes all shears, moments, deflections, camber, settlement of support, investigations, etc.

Any sound method of design, even when used in conjunction with relatively rough calculation, is far more accurate than the assumptions of dead load and live load applied to the structure. For instance, reinforced concrete is usually assumed to weigh 150 lb per cu ft. If this varies even 1.5 lb per cu ft, the dead load of the concrete would be inaccurate 1 per cent. Even structural steel will vary in weight from the theoretical, and live loads on most structures can and do vary widely from the assumed live load. This is not intended to imply that the calculations can be as erroneous as the assumption for load, but it is intended to show that the method used in the analysis is perhaps the most accurate part of the design even when handicapped with relatively rough calculations.

A. A. EREMIN,[12] ASSOC. M. AM. SOC. C. E. (by letter).—A method of analyzing stresses in continuous trusses by computing bending moments at the supports is presented in this paper. Mr. Epps has cited various advantages of the method over the conventional method in which the reaction forces must be computed. These advantages are even more numerous than those indicated. As long ago as 1930 Prof. G. G. Krivoshein showed that, by computing bending moments at the supports of continuous trusses, the results will be more accurate than by computing the redundant forces at the supports.[13] Professor Krivoshein developed various equations for computing bending moments at the supports.

The elastic properties of continuous trusses may be expressed by:

$$\frac{I}{I_0} = \left(\frac{d}{d_0}\right)^3 \qquad (10)$$

in which, I and d are moment of inertia and depth of truss at any section, respectively; and I_0 and d_0 are some arbitrarily selected moment of inertia and depth of truss, respectively.

In some trusses Professor Krivoshein stated that satisfactory results may be obtained with the exponent in Equation (10) equal to 2.5 instead of 3. Obviously, Equation (10) is exactly the same as that generally used in the analysis of stresses in continuous beams of solid cross-section and constant width. It is interesting to note that this formula may also be used in computing the constants of continuous trusses.

Mr. Epps computes the elastic weights of continuous trusses by means of the radii. However, a more direct computation may often be made by means of formulas previously cited by the writer,[14] in which the elastic weights are computed directly from the angular relation between truss members at each joint. Furthermore, the terms in the writer's equation[14] may also be used for analyzing secondary stresses in the trusses, thus saving time when additional computations for the complete analysis of stresses is required.

LEO LEGENS,[15] ESQ. (by letter).—The author shows quite well the limitations of the method of redundant reactions as applied to continuous girders, and also the much greater simplicity of calculation in using the moments over the piers as the redundants. However, he does not show any relationship to the calculation of influence lines by Müller-Breslau's equations.[16] The writer would like to show the application of these equations to the three-span continuous beam of Fig. 2. The moment of inertia of this beam is constant for all spans, which simplifies the calculations as compared to a girder of variable section or truss.

[16] "Graphische Statik der Baukonstruktionen," by Müller-Breslau, Band II, Abteilung, 1908 Edition, p. 104 *et seq.*

The Müller-Breslau equation[16] states that:

$$X_a\,\delta_{aa} + X_b\,\delta_{ab} \cdots = \Sigma\, P_m\,\delta_{ma} \ldots\ldots\ldots\ldots\ldots (11)$$

The statically indeterminate parameters X_a, X_b, $\cdots$ are to be chosen so that the deflection curves may be obtained easily and so that the deflections $\delta_{aa}\delta_{ab}\cdots$ will vanish if possible.

Moment diagrams $M_a\,M_b \cdots$ produced by $X_a = -1$, $X_b = -1 \cdots$ should be of simple forms (rectangles, triangles, or parabolas) for which Müller-Breslau[16] has indicated a rapid method of finding the deflections δ_{ma}, δ_{mb}, $\cdots$ with the values ω_R, ω_D, ω_P and ω_P''. These deflections are:

For Fig. 11:

$$E\,I\,y = \frac{z\,l^2}{2}\,\omega_R \ldots\ldots\ldots\ldots\ldots\ldots (12a)$$

in which $\omega_R = \frac{x}{l} - \frac{x^2}{l^2}$; and, for Fig. 12:

$$E\,I\,y = \frac{z\,l^2}{6}\,\omega_D \ldots\ldots\ldots\ldots\ldots\ldots (12b)$$

in which $\omega_D = \frac{x}{l} - \frac{x^3}{l^3}$; and, for Fig. 13:

$$\delta_{ii} = \int M_i^2\,dx = \frac{l}{3}\,(y_1^2 + y_1\,y_2 + y_2^2) \ldots\ldots\ldots\ldots (12c)$$

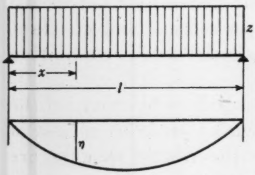

FIG. 11

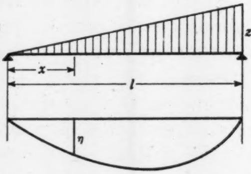

FIG. 12

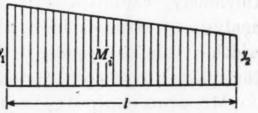

FIG. 13

In this problem only one indeterminate parameter, $X_a = R_1$, is introduced and the beam is treated as a two-span continuous girder (see Fig. 14(a)). Parameter $X_a = -1$ produces bending moments M_{1a} and M_{a2} at Supports 1 and 2 which may be calculated by the equation of three moments of Clapeyron:

$$M_{1a}\,l_2 + 2\,M_{2a}\,(l_2 + l_3) = 0 \ldots\ldots\ldots\ldots\ldots (13a)$$

and

$$M_{1a} = -1 \times l_1 = -60 \ldots\ldots\ldots\ldots\ldots\ldots (13b)$$

Therefore, $M_{2a} = \frac{l_1\,l_2}{2\,(l_2 + l_3)} = \frac{60 \times 72}{2 \times 132} = 16.36.$

The parameter X_a is equal to $\frac{\delta_{ma}}{\delta_{aa}}$ for a load of $P_{m=1}$. Since the deflection curve for a load $X_a = -1$ is the δ_{ma} line, the deflection curve for a load $\frac{1}{\delta_{aa}}$ is the influence line for $X_a = R_1$.

According to Fig. 13: $E\,I\,\delta_{aa} = \int M_a^2\,dx = \frac{60}{3} \times 60^2 + \frac{72}{3}(60^2 - 60 \times 16.36 + 16.36^2) + \frac{60}{3} \times 16.36^2 = 146\,300$; $z_1 = -\frac{60}{146\,300} = -0.000140$; and, $z_2 = +\frac{16.36}{146\,300} = +0.000111$. Finally the ordinates of the X_a-line (see Fig. 14(d)) according to Figs. 11 and 12 are:

FIG. 14

$$y_1 = \frac{x_1}{l_1} - \omega_D \times 0.000410\,\frac{l_1^2}{6} = \frac{x_1}{l_1} - 0.246\,\omega_D \quad \text{........} (14a)$$

$$y_2 = \omega_R \times 0.000410\,\frac{l_2^2}{2} + \omega_D\,(0.000410 + 0.000111)\,\frac{l_2^2}{6}$$

$$= -1.06\,\omega_R + 0.45\,\omega_D \quad \text{..................} (14b)$$

and

$$y_3 = \omega_D \times 0.000111\,\frac{l_3^2}{6} = +0.066\,\omega_D \quad \text{............} (14c)$$

The values for ω_R and ω_D may be written rapidly, even without the aid of a table:

For $\frac{x}{l} = 0.2$

$$\omega_R = 0.2 - 0.2^2 = 0.16; \quad \text{and,} \quad \omega_D = 0.2 - 0.2^3 = 0.192$$

for $\frac{x}{l} = 0.5$

$$\omega_R = 0.5 - 0.5^2 = 0.25; \quad \text{and,} \quad \omega_D = 0.5 - 0.5^3 = 0.375$$

and for $\frac{x}{l} = 0.8$

$$\omega_R = 0.8 - 0.8^2 = 0.16; \quad \text{and,} \quad \omega_D = 0.8 - 0.8^3 = 0.288.$$

These values substituted in the equations for y_1, y_2 and y_3 give the same values for the influence line for R_1 as those shown in Fig. 2. This is a very simple and quick method of computing the influence line for a three-span continuous girder as it allows the use of a slide-rule for all computations.

For a multiple-span girder the writer recommends (as does the author) using the bending moments over the supports as redundants. Thus one can apply the equations of three moments, and the deflection curves are computed for each span separately with the values of ω_D, assuming a constant value of I.

Müller-Breslau[16] presents a large number of examples demonstrating simple methods of computing such systems.

George L. Epps,[17] Assoc. M. Am. Soc. C. E. (by letter).—In view of the specialized and rather narrow field covered by this paper the writer is quite pleased with the discussion presented and appreciates the efforts put forth by the discussers. They have brought out some very helpful ideas and criticisms.

While the writer based his theoretical explanation on the Müller-Breslau equation, Mr. Deans shows that the procedure also satisfies Maxwell's law of reciprocal deflections. This undoubtedly will be of aid to some engineers who may be more familiar with the application of the latter principles.

In the second part of his discussion Mr. Deans applies the column analogy to continuous trusses. The writer worked from the column analogy in developing this method with the feeling that he was getting a more usable and also somewhat simpler tool of design. That is, the calculations proceed directly to the determination of the fixed-end moments, stiffness, and carry-over factors with one set of computations for each end of the beam, whereas in column analogy it is necessary to make a separate set of calculations for each of the stiffnesses, carry-over factors, and fixed-end moments for each end of the beam.

Mr. Deans requested that the writer comment upon the application of the method to multiple-trussed arches. The writer has had no occasion to make a careful study of this subject, but he sees no reason why it should not be possible to extend the method to include such problems.

Mr. Lamb, in his discussion, raises several objections to the method presented by the writer. First he states it is more difficult to determine influence lines for the individual members of the truss when using the pier moments as redundants than when using the reactions as redundants. There is no difference in the work after the reaction influence lines are obtained. Therefore, it may be enlightening to examine the procedure for obtaining the reaction influence lines.

Using the reactions as redundants, it is necessary to calculate the deflection of each panel point for the entire length of the bridge with a unit load at each of the intermediate piers in turn and no reaction at the other intermediate piers. In a four-span, symmetrical bridge this means that one set of deflections must be calculated for the entire bridge with a unit load at the first pier and another set for half the bridge with the unit load at the center pier. Thus deflections must be calculated for six spans. Using these deflections the reaction influence lines are obtained as outlined by Mr. Lamb in the last part of his discussion.

---

[17] Senior Engr., Design Dept., State Highway Comm., Topeka, Kans.

Making the moments the redundants, it is necessary to calculate the deflections for the first span once and for the second span twice. This makes it necessary to calculate the deflections for only three spans, or half as many as for redundant reactions, as already mentioned. These deflections are the ordinates of the influence lines for fixed-end moments. The calculations necessary for the slope-deflection equations, pier moments, and reactions may be made easily in less time than is required to calculate the deflections of three spans. Thus it is evident that a good deal of time is saved using the pier moments as redundants.

Mr. Lamb's second objection deals with the subject of the settlement of supports. The effect upon the structure of raising or lowering any support is easily calculated, using the slope-deflection equations which give the moments at the piers.

Mr. Lamb's third and fourth objections deal with cambering of the truss and the calculations necessary for obtaining the proper camber. The writer agrees with Mr. Lamb that a little changing in the form of tabulation will simplify the calculation of elastic weights for camber.

Mr. Lamb states that he prefers to use the method of angle changes in computing elastic weights, whereas the writer used radii of the members. In Mr. Lamb's example, Table 3, Column (6), the term $\frac{h}{\sec \phi}$ is equal to the radius r, as used by the writer, thus showing that Mr. Lamb was using practically the same method as the writer in obtaining the elastic weights.

Mr. Lamb's method of calculating influence lines for reactions will remove the objection raised by the writer to the large numbers involved in the method of redundant reactions as presented by Mr. Pierce[2] for the case of uniform moment of inertia throughout the beam. However, for variable depth of beam or truss work, complications arise. After Equations (7*a*) and (7*b*) are solved for the reactions as shown in Fig. 10, it is necessary to find the deflected line of the beam which involves calculations similar to those shown in Tables 1 and 2, extended to include the entire girder from *A* to *B*. These calculations, while not difficult, consume almost as much time as is required for the complete analysis by distributing moments or slope deflection, to say nothing of the time required before solving Equations (7*a*) and (7*b*).

It is also possible to use Mr. Pierce's method to find the necessary influence ordinates. Of course, this again introduces the large numbers just mentioned. It should be noted that Mr. Lamb's method is essentially the same as Mr. Pierce's down to the solution of Equations (7*a*) and (7*b*).

Mr. Legens presents another variation of the method of redundant reactions for uniform moment of inertia. This also eliminates the large numbers and should be quite useful for the special case of beams of uniform cross-section. However, it becomes almost impossible for use with trusses or beams with haunches.

Mr. Eremin might well have enlarged upon his remarks. The work of Prof. G. G. Krivoshein is not familiar to the writer or his associates and could no doubt have been quoted more fully here. Equation (10), presented by Mr. Eremin, will undoubtedly be useful in preliminary design, but it would be well to use a more exact calculation for final designs.

SOLUTION OF EQUATIONS IN STRUCTURAL ANALYSIS BY CONVERGING INCREMENTS

By George H. Dell,[1] Assoc. M. Am. Soc. C. E.

With Discussion by Messrs. A. Floris, L. E. Grinter, A. A. Eremin, and George H. Dell.

Synopsis

A method of solving equations in structural analysis by converging increments (which is related to the process of successive substitutions) is demonstrated in this paper. The method is also useful as a guide in developing alternate solutions, of the moment-distribution type, in cases where the proper mode of performing the distributions may not be otherwise readily apparent.

Introduction

The past decade has witnessed the widespread adoption of the masterly method of moment-distribution,[2] introduced to the Society by Hardy Cross, M. Am. Soc. C. E., in 1930, which has resulted in dispelling to an unprecedented extent the practical difficulties formerly associated with the subject of statically indeterminate structures. At the same time, the new "movement" has produced a stimulation of interest in the older, algebraic methods of analysis, such as three-moment equations, area moments, slope deflection, etc.

This interest appears to be justified. Many individuals have a natural preference for algebraic methods. Besides, the fact that algebraic procedure has played an important rôle in indeterminate analysis in the past would seem to provide grounds for supposing that these methods will continue to exercise a strong appeal to writers and students for a long time to come. However, algebraic analysis has been somewhat handicapped by a scarcity of practical methods of solving the simultaneous equations. Precise methods generally require too much time; hence, the process of successive substitutions, or iteration, has been used to a considerable extent. The latter method is open to the criticisms that it is lacking in form and is applicable to only the most rapidly converging types of equations.

Note.—Published in October, 1938, *Proceedings*.

[1] Associate in Civ. Eng., Univ. of Illinois, Urbana, Ill.

[2] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 1.

Herein, the writer will attempt to show that the method of converging increments provides an easy, rapid, orderly, and accurate means of solving the equations encountered in a large variety of structural problems; and, furthermore, that it can always be used as a guide to the development of alternate solutions of the distribution type, thereby extending the advantages of this form of solution to new problems in which the distribution ratios cannot be readily determined by inspection. (Applications of the method of converging increments to problems in least squares were described by the writer in 1935.)[3]

EXPLANATION AND APPLICATION OF THE METHOD

The method of converging increments, which is related to the process of iteration, is applicable to systems of simultaneous equations in which each of the several unknowns is strongly represented by a particular equation. As most persons who have worked with the iteration process have doubtless observed, after the completion of a few cycles of substitutions, such systems generally begin to converge with approximately equal rates in the separate equations. When this stage is reached, in the method of converging increments, the solution is brought to a conclusion. If the rate of convergence is rapid, the computations already made are added and the values of the unknowns immediately ascertained. If the rate of convergence is slow, the values of the remaining cycles of figures are computed by series summation, thus making possible a considerable saving in time, while preserving a relatively high degree of precision in the results.

A general derivation of the method as applied to diagonally symmetrical systems has been given elsewhere.[3] The derivation is equally valid for nonsymmetrical systems.

The method is ideally adapted to the use of the slide-rule as each successive line in the solution is computed with a single setting of the slide, and the precision of the method as a whole is consistent with that of the slide-rule.

In order to illustrate the application of the method to problems in structural analysis, three examples are given. For Examples 1 and 2, a continuous beam is solved by means of three-moment equations and also by slope-deflection equations. These examples are used to represent the case of rapidly converging equations. Example 3, which deals with a crane-girder bent, is used to represent the case of slowly converging equations.

Example 1.—The equation of three moments for a continuous beam on unyielding supports and with modulus of elasticity constant throughout, may be written in the form:

$$M_0 K_2 + 2 M_1 (K_1 + K_2) + M_2 K_1 = -\frac{6 \bar{x}_1 A_1 K_2}{L_1^2} - \frac{6 \bar{x}_2 A_2 K_1}{L_2^2} \ldots (1)$$

in which (as shown in Fig. 1): M_0, M_1, and M_2 = the bending moments at the left, center, and right supports, respectively; K_1 and K_2 = the relative $\frac{I}{L}$-values of the left and right spans, respectively; I = moment of inertia;

---

[3] "The Adjustment of a Level Net," by George H. Dell, Assoc. M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 834.

L_1 and L_2 = the lengths of the left and right spans, respectively; $\bar{x}_1$ and $\bar{x}_2$ = the distances from the outer supports to the centroids of the two moment diagrams, the spans being considered as simple beams; and, A_1 and A_2 = the areas of the simple-beam moment diagrams on the left and right spans, respectively. Equation (1) may also be written:

$$M_0 K_2 + 2\,M_1 (K_1 + K_2) + M_2 K_1 \\ = K_2 (C_{01} + 2\,C_{10}) + K_1 (2\,C_{12} + C_{21})$$

in which C_{01}, C_{10}, etc., the fixed-end moments, are positive for tension in lower fibers.

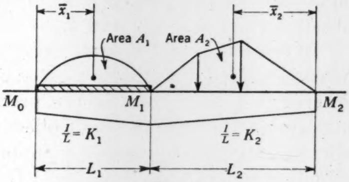

FIG. 1

For the continuous beam shown in Fig. 2, $\frac{\bar{x}_1}{L_1} = \frac{\bar{x}_2}{L_2} = \frac{1}{2}$, and Equation (1) may be written:

$$M_0 K_2 + 2\,M_1 (K_1 + K_2) + M_2 K_1 = -\frac{3\,A_1 K_2}{L_1} - \frac{3\,A_2 K_1}{L_2} \ldots\ldots (2)$$

The relative values of K for the various spans of the continuous beam are shown in parentheses in Fig. 2. Upon applying Equation (2) to successive pairs of adjacent spans in this continuous beam, the following system of equations is obtained:

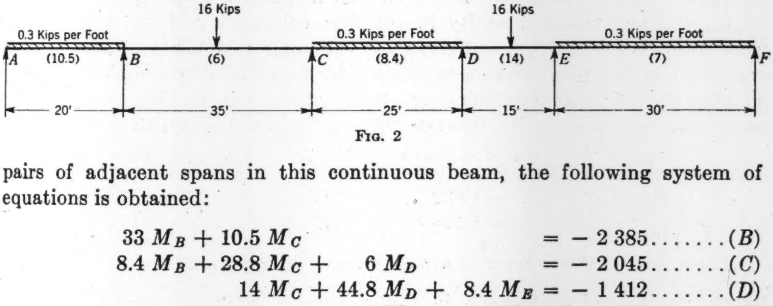

FIG. 2

$$\begin{aligned} 33\,M_B + 10.5\,M_C \qquad\qquad\qquad\qquad &= -\,2\,385 \ldots\ldots (B) \\ 8.4\,M_B + 28.8\,M_C + \quad 6\,M_D \qquad\qquad &= -\,2\,045 \ldots\ldots (C) \\ 14\,M_C + 44.8\,M_D + \ 8.4\,M_E &= -\,1\,412 \ldots\ldots (D) \\ 7\,M_D + \ \ 42\,M_E &= -\,1\,575 \ldots\ldots (E) \end{aligned}$$

Preliminary to solving, Equations (*B*) to (*E*) are written in columns, as shown in Table 1(*a*). In the following description, Lines Nos. 1, 2, 3, and 4, Table 1, will be referred to as the "first line of the equations," the "second line of the equations," etc. It will be noted that the strong coefficient in each of the equations is underlined.

The arrangement of the solution is shown by the first set of calculations (see Table 2(*a*)), which (for a system of four equations) consists of the first four lines of the solution. In Line No. 1, Table 2(*a*), the underlined quantity, $-\,\underline{2\,385}$, is the value of the right-hand term of Equation (*B*). This quantity is extended horizontally in proportion to the coefficients in the first line of the equations, namely, $\underline{33}$, 8.4, 0, and 0. In Line No. 2, the underlined quantity is first computed by subtracting − 607 (in Line No. 1) from − 2 045 (the right-hand term of Equation (C)), giving − 1 438. This value is then extended horizontally in proportion to the coefficients of the second line of the equations, namely, 10.5, 28.8, 14, and 0. A similar procedure is followed in obtaining Lines Nos. 3 and 4.

In ensuing sets, the same order of operation is observed as in the first set. The underlined quantity in a given column is equal to the sum of the extensions entered in that column in the preceding lines of the solution below the last underscored extension, multiplied by − 1. The underlined quantities are always extended horizontally in proportion to the coefficients in the corresponding line of the equations. In this manner, the second and third sets of calculations are found to be as given in Tables 2(b) and 2(c).

Ordinarily, the foregoing process should be continued until the underlined quantities in the final set are found to be in a practically constant ratio with respect to the corresponding quantities of the preceding set (or until the extended items become negligible). Inspection of the computations in Table 2 shows that up to the third set such a condition has not been attained. Accordingly, a fourth set of calculations is made, as shown in Table 2(d).

It is now evident that in the second, third, and fourth columns of the calculations, the terms, − 8, 5, and − 1 are each about one-fifth of the corresponding quantities in the third set, namely, − 45, 32, and − 5, respectively. In the first column, this ratio does not hold; on the contrary, an apparent divergency exists. However, it is seen that if a fifth set of calculations were begun, the underlined quantity in the first column would be + 3, which, when compared to + 16, would give these values approximately the same ratio, or rate of convergence, as has been attained by the remaining columns. Consequently, the solution is terminated at the end of Set 4. The sums of the underlined quantities in the separate columns in Sets 1 to 4, inclusive, are:

Equation	Sum of underlined quantities in Table 2	Equation	Sum of underlined quantities in Table 2
(B)...........	− 1 832	(D)...........	− 366
(C)...........	− 1 528	(E)...........	− 1 518

The values of the unknowns are then found by dividing the foregoing sums by the underlined coefficients in the respective equations: $M_B = \frac{-1\,832}{33} = -55.5$; $M_C = \frac{-1\,528}{28.8} = -53.1$; $M_D = \frac{-366}{44.8} = -8.16$; and, $M_E = \frac{-1\,518}{42} = -36.1$.

Example 2.—In the slope-deflection method the expression for the bending moment at Point A in Member $A\,B$, in terms of the deformations, is given by Equation (3):[4]

$$M_{AB} = 2\,E\,K\,(2\,\theta_A + \theta_B - 3\,R) + C \dots\dots\dots\dots (3)$$

in which E = the modulus of elasticity; K = the value of the ratio $\frac{I}{L}$ (moment

of inertia divided by the length) for the member; θ_A, θ_B = the changes in slope of the elastic curve at Point A and at Point B, respectively, from its initial position; R = the ratio of deflection to length of member; and, C = the fixed-end moment at Point A due to external transverse forces acting on the member.

A somewhat more convenient form for Equation (3) is obtained by means of the substitutions: $A = 2\,E\,\theta_A$; $B = 2\,E\,\theta_B$; and, $\lambda = 6\,E\,R$. Equation (3) may then be written as follows:

$$M_{AB} = K\,(2\,A + B - \lambda) + C \quad \ldots\ldots (4)$$

For a continuous beam on unyielding supports the quantity, λ, is equal to zero in each span. In accordance with Equation (4), the bending moments at the supports of the continuous beam in Fig. 2 may then be expressed as follows:

$$M_{AB} = 10.5\,(2\,A + B) - 10 \quad \ldots\ldots (5a)$$

$$M_{BA} = 10.5\,(A + 2\,B) + 10 \quad \ldots\ldots (5b)$$

$$M_{BC} = 6\,(2\,B + C) - 70 \quad \ldots\ldots (5c)$$

$$M_{CB} = 6\,(B + 2\,C) + 70 \quad \ldots\ldots (5d)$$

$$M_{CD} = 8.4\,(2\,C + D) - 15.62 \quad \ldots\ldots (5e)$$

$$M_{DC} = 8.4\,(C + 2\,D) + 15.62 \quad \ldots\ldots (5f)$$

$$M_{DE} = 14\,(2\,D + E) - 30 \quad \ldots\ldots (5g)$$

$$M_{ED} = 14\,(D + 2\,E) + 30 \quad \ldots\ldots (5h)$$

$$M_{EF} = 7\,(2\,E + F) - 22.5 \quad \ldots\ldots (5i)$$

and,

$$M_{FE} = 7\,(E + 2\,F) + 22.5 \quad \ldots\ldots (5j)$$

Upon putting $\Sigma M = 0$ at each of the joints, the following equations of static equilibrium (which may be written by inspection) are obtained:

$$\begin{aligned}
21\,A + 10.5\,B &= 10.00 \ldots (6a)\\
10.5\,A + 33\,B + 6\,C &= 60.00 \ldots (6b)\\
6\,B + 28.8\,C + 8.4\,D &= -54.38 \ldots (6c)\\
8.4\,C + 44.8\,D + 14\,E &= 14.38 \ldots (6d)\\
14\,D + 42\,E + 7\,F &= -7.50 \ldots (6e)\\
7\,E + 14\,F &= -22.50 \ldots (6f)
\end{aligned}$$

By combining Equations (6a) and (6b), (6e) and (6f), the following system of equations in four unknowns results:

$$\begin{aligned}
27.75\,B + 6\,C &= 55.00 \ldots\ldots (6b')\\
6\,B + 28.8\,C + 8.4\,D &= -54.38 \ldots\ldots (6c)\\
8.4\,C + 44.8\,D + 14\,E &= 14.38 \ldots\ldots (6d)\\
14\,D + 38.5\,E &= 3.75 \ldots\ldots (6e')
\end{aligned}$$

Using the procedure already described, the re-arrangement of the equations is shown in Table 1(*b*) and the solution in Table 3. At the end of the third set of computations, the solution shows the following rates of convergence: First column, $\frac{1.94}{13.80} = 0.14$; second column, $\frac{-1.39}{-9.30} = 0.15$; third column, $\frac{0.99}{5.17} = 0.19$; and, fourth column, $\frac{-0.31}{-1.61} = 0.19$.

The sums of the underlined quantities are given below the third set in Table 3, and the values of the unknowns are: $B = \frac{70.74}{27.75} = 2.55$; $C = \frac{-76.97}{28.8} = -2.67$; $D = \frac{39.87}{44.8} = 0.891$; and, $E = \frac{-8.69}{38.5} = -0.226$.

The values of the unknowns A and F may then be found from Equations (6*a*) and (6*f*), respectively. Substitution of the values of the unknowns in Equations (5*b*) to (5*i*), inclusive, gives the following values for the bending moments: $M_{BA} = 55.18$; $M_{BC} = -55.42$; $M_{CB} = 53.26$; $M_{CD} = -53.00$; $M_{DC} = 8.14$; $M_{DE} = -8.22$; $M_{ED} = 36.14$; and $M_{EF} = -36.12$.

The small discrepancies in the two solutions are due to slide-rule inaccuracies and to the neglect of small residuals in the calculations. The latter could have been taken into account, in the manner to be explained in connection with Example 3. Familiarity with the method of doing this enables one readily to determine that by neglecting these residuals the errors in the unknowns would be within 1 per cent.

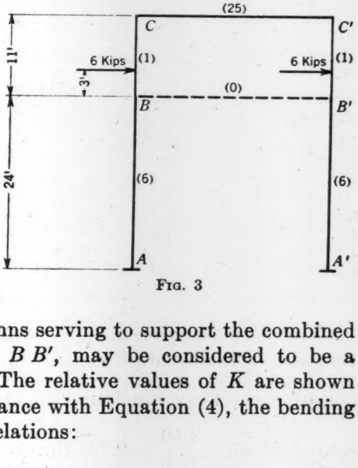

FIG. 3

Example 3.—The crane-girder bent shown in Fig. 3, with slight modification, is the same as that analyzed elsewhere[5] by Harold E. Wessman, M. Am. Soc. C. E. The roof truss is represented by Line $C\,C$; $B\,C$ and $B'\,C'$ are the roof columns; and $A\,B$ and $A'\,B'$ are the columns serving to support the combined roof and crane loads. The dotted line, $B\,B'$, may be considered to be a "dummy" member, with zero stiffness. The relative values of K are shown in parentheses in the diagram. In accordance with Equation (4), the bending moments are expressed by the following relations:

$$M_{AB} = 6\,(B - \lambda_1) \qquad \text{(7a)}$$

$$M_{BA} = 6\,(2\,B - \lambda_1) \qquad \text{(7b)}$$

$$M_{BC} = 1\,(2\,B + C - \lambda_2) - 9.52 \qquad \text{(7c)}$$

$$M_{CB} = 1\,(B + 2\,C - \lambda_2) + 3.57 \qquad \text{(7d)}$$

and,

$$M_{CC'} = 25\,(3\,C) \qquad \text{(7e)}$$

---

[5] *Transactions*, Am. Soc. C. E., Vol. 96 (1932), Fig. 22, p. 49.

Equations (8) may now be written to express the necessary conditions of equilibrium in the structure:

$$14\,B + C - 6\,\lambda_1 - \lambda_2 = 9.52 \ldots\ldots\ldots\ldots (8a)$$

$$B + 77\,C - \lambda_2 = -3.57 \ldots\ldots\ldots\ldots (8b)$$

$$-6\,B + 4\,\lambda_1 = 48.00 \ldots\ldots\ldots\ldots (8c)$$

and,

$$-B - C + 0.667\,\lambda_2 = 4.02 \ldots\ldots\ldots\ldots (8d)$$

The solution of Equations (8) proceeds in the same manner as in the previous examples, four sets of calculations being required to secure a uniform rate of convergence, as shown in Table 4.

....	9.52	−3.57	48.00	4.02	....	....	....	....	....	....	....	....

TABLE 4.—(*Continued*)

Line No.	(d) THIRD SET				(e) FOURTH SET			
	(B)	(C)	(λ_1)	(λ_2)	(B)	(C)	(λ_1)	(λ_2)
1.....	63.87	4.57	−27.40	−4.57	47.98	3.43	−20.55	−3.43
2.....	0.05	4.56	....	−0.05	....	3.50	....	−0.05
3.....	−41.10	....	27.40	....	....	....	20.55	....
4.....	−6.93	−6.93	....	4.62	....	....	....	3.48

Upon the completion of the fourth set of calculations the rates of convergence in the separate columns are compared, to determine their degree of uniformity. They are found to be as follows: First column, $\frac{47.98}{63.87} = 0.75$; second column, $\frac{3.50}{4.56} = 0.75$; third column, $\frac{20.55}{27.40} = 0.75$; and, fourth column, $\frac{3.48}{4.62} = 0.75$.

Experience indicates that if the range of discrepancy in these ratios is within approximately 0.05, the remaining terms may generally be estimated by series summation without excessive error. If the desired agreement had not been attained at the end of the fourth set, it would have been necessary to calculate one or more additional sets.

In order to effect the summation by geometrical series, the average rate of convergence and the summation factor are required. In general, the average rate of convergence (denoted by the letter symbol, r) is best determined by dividing the sum of the underlined quantities in the last set of calculations by the sum of the corresponding quantities in the preceding set. In finding these two sums, the additions are performed without regard to sign; that is, the absolute sum is used. The summation factor is then given by the ratio, $\frac{r}{1-r}$ (the common formula for the sum of the infinite convergent series, $ar + ar^2 + ar^3 + \cdots$ being $\left.\frac{ar}{1-r}\right)$.

In Example 3 the sum of the underlined quantities in the fourth set is $47.98 + 3.50 + 20.55 + 3.48 = 75.51$; the sum of the underlined quantities in the third set is $63.87 + 4.56 + 27.40 + 4.62 = 100.45$; the average rate of convergence is $r = \frac{75.51}{100.45} = 0.75$; and the summation factor is $\frac{0.75}{0.25} = 3.00$.

The approximate sums of the quantities not included in the first four sets of calculations are then found by multiplying the underlined quantities of the final set by the summation factor, as follows: First column, $47.98 \times 3.00 = 143.94$; second column, $3.50 \times 3.00 = 10.50$; third column, $20.55 \times 3.00 = 61.65$; and, fourth column, $3.48 \times 3.00 = 10.44$.

The results of the series summations are then added to the underlined quantities that have been determined directly, and the values of the unknowns are found, as before, by dividing by the underlined coefficients in the respective equations, as shown in Table 5.

The solution of the problem is concluded by substituting the values of the unknowns in Equations (7), the following bending moments being thus found: $M_{AB} = -147.12$; $M_{BA} = 3.06$; $M_{BC} = -3.06$; $M_{CB} = -14.91$; and, $M_{CC'} = 14.70$.

TABLE 5.—DETERMINATION OF UNKNOWNS, EXAMPLE 3

Column:	First set	Second set	Third set	Fourth set	Series	Totals	Divisors	UNKNOWNS	
								Equation	Values
First....	9.52	85.14	63.87	47.98	143.94	350.45	14	(B)	25.03
Second ..	−4.25	0.88	4.56	3.50	10.50	15.19	77	(C)	0.196
Third ...	52.08	36.50	27.40	20.55	61.65	198.18	4	(λ_1)	49.55
Fourth ..	4.64	6.09	4.62	3.48	10.44	29.27	0.667	(λ_2)	43.90

In order that the relative accuracy of the method of converging increments in the present instance may be judged, the following results of a precise solution are given: $B = 25.043$; $C = 0.198$; $\lambda_1 = 49.564$; and $\lambda_2 = 43.893$.

The precision of the solution can be increased by computing the errors in the equations resulting from a first solution and using these, with reversed signs, as a new series of right-hand terms for making a few additional sets of calculations. In determining the errors in the equations at any stage of the solution, the appropriate quantities may be extended horizontally, as in the solution itself. If the utmost precision is desired, these extensions should be computed with accuracy.

In order to avoid mistakes in the solution it is desirable that the computations be checked frequently. One method of checking consists in making a careful review of each line before proceeding further. Another method makes use of an additional column of figures throughout. For the equations themselves this column contains the algebraic sum of the coefficients in a given horizontal line. In the solution, these sums are used to secure an additional extension in each line, which should agree with the algebraic sum of the remaining quantities in that line. Additions may be checked by inserting after each set a line of figures consisting of the sums of the quantities which follow the underlined item in each column of the given set; the aggregate of these sums provides a cross-check on the control column from set to set.

THE ALTERNATE SOLUTION

If the calculations resulting from a solution of a given problem by the foregoing method are recorded, step by step, on a diagram of the structure in proximity to the joints or members to which they pertain, an alternate solution possessing a number of the characteristics of the method of moment-distribution will be obtained. A detailed comparative analysis of the two solutions then enables one readily to determine the correct manner of performing the distributions, so that additional problems of the same type may be solved by use of the alternate method alone. A procedure is thus provided for extending the method of distributions to various forms of problems in which the correct distribution ratios may not be initially obvious.

FIG. 4

In order to illustrate the foregoing statements, the solution of the equations of Example 1 is written below the various supports of the continuous beam in Fig. 4.

Comparison of the extended quantities with the coefficients of the equations in Example 1 (Table 1(*a*)) shows that the portion of the first numerical value appearing under Support B ($-$ 2 385) which is to be distributed to the adjacent support depends upon the ratio of the stiffness of Span $C\,D$ to the value of $2\,\Sigma\,K$ at Joint B. Similar ratios for performing the distributions at the remaining supports are indicated in parentheses in Fig. 4. In this example, the entire process of developing the alternate solution is readily followed by referring to the original solution (Table 2), and need not be described in further detail.

In order to illustrate the method of developing the alternate solution in problems in which the unknowns of the simultaneous equations are dependent upon auxiliary equations, Example 2 will be used.

The solution is begun by writing the fixed-end moments adjacent to the various supports in Fig. 5. In accordance with Equations (6a) and (6b), and (6e) and (6f), the fixed-end moments at the supports at the two extremes of the beam are divided by $-$ 2 and then brought over to the adjacent support. The moments at the various supports are then added, with change in sign

FIG. 5

(giving the right-hand terms of Equations (6b'), (6c), (6d), and (6e'), respectively), and the first set of calculations, as given by the original solution (Table 3), is written beneath the appropriate supports of the continuous beam in the diagram.

In starting the analysis of the extended items, it is seen upon examination of the original solution, that the part of the first moment (+ 55.00) which goes over to the right-hand end of Span $B\,C$ depends upon the ratio of the stiffness of that span to the quantity, 27.75. The latter quantity, according to Equations (6a), (6b), and (6b'), is equal to $2\,\Sigma\,K$ at Joint B, less $0.5\,K_{AB}$. In a similar manner, the form and significance of the remaining ratios are determined, as shown in parentheses in Fig. 5.

After the second and third sets of computations are entered on the diagram, the bending moments are ready to be calculated. This step could be done in the manner that was followed in the original solution—that is, by adding the underlined quantities, dividing by the underlined coefficients of the corresponding equations, and then substituting in the auxiliary formulas, Equations (5*c*) to (5*h*), inclusive.

However, at this point it is desirable to inquire into the significance of the extended quantities. Again referring to the original solution, it will be seen that the first extended item—namely, $11.90 \left(= \frac{6}{27.75} \times 55.00 \right)$—represents a part of the term, $6\,B$, in Equation (5*d*), and hence may be used in computing M_{CB}. Therefore, this quantity was written to the left of Support *C*. Similar reasoning governed the recording of the remaining extensions to the right or to the left of the supports, as shown in Fig. 5. Accordingly, in order to find the bending moments, the underlined quantities were ignored (and might well have been omitted from Fig. 5), and the extended items were added, giving: − 16.03, 15.31, 7.47, − 22.45, − 3.15, and 12.44 (see Fig. 5). Examination of the original solution shows that these quantities are equal to $6\,C$, $6\,B$, $8.4\,D$, $8.4\,C$, $14\,E$, and $14\,D$, respectively (in which the coefficients are the *K*-values of the various spans). By reference to Equations (5*c*) to (5*h*), inclusive, the remaining part of the calculation shown in Fig. 5 will be readily followed.

It is thus seen that, in problems of the type represented by Example 2, the method of converging increments not only solves the unknowns of the simultaneous equations, but actually evaluates the auxiliary equations at the same time.

CONCLUSION

Although the examples presented herein have been confined to structures involving only four equations in their analysis, the method that has been illustrated in the solution of the equations may be applied successfully to more complicated problems, provided, of course, that the analytical method on which the solution is based yields equations that are sufficiently convergent.

In many cases the rate of convergence can be improved materially by a simple re-arrangement of the equations. In determining bending moments produced by horizontal forces in multi storied structures an effective device consists in replacing each joint equation with a combined shear-and-joint equation. Doing this with Example 3, for instance, the rate of convergence is changed from 0.75 to 0.565, and the summation factor is reduced from 3.00 to 1.30.

DISCUSSION

A. Floris,[6] Esq. (by letter).—An ingenious method for solving a certain type of simultaneous linear equation by successive approximations is presented by the author. In these equations the major coefficients (that is, those belonging to the principal diagonal of the matrix) are appreciably greater than the other coefficients. A more refined criterion of these equations has been given by E. von Mises and H. Polaczek-Geiringer.[7]

The method of converging increments is in reality the mathematical counterpart of the statical analysis of moment distribution. It is exactly the same method as that developed by J. Morris in 1935.[8] The difference between the two is slight and consists mainly in the manner of presenting the subject and the arrangement of the equations. However, the speeding up of the calculations by series summation in case of slow converging equations is shown only by Professor Dell.

The method of converging increments is not an improvement over ordinary iteration.[9] The principal advantage in the use of iteration lies in the fact that, in each step or cycle, an approximate value of the unknowns is determined, which can be improved further by repeating the process. This important advantage can be realized in the author's method only by additional labor. For this purpose the underlined values must be added at the end of each cycle and then divided by the corresponding major coefficients in order to obtain the values of the unknowns. Unless these checks are made, errors that creep in during the distribution will remain unnoticed. Such intermediate calculations are not necessary in the ordinary method of iteration.

Inasmuch as the simultaneous equations encountered in structural analysis are usually very sensitive, the method of converging increments, in certain cases, may make the process extremely lengthy or divergent. The criterion for such cases is given by Mr. Morris.[8]

The assumed values of the unknowns in the ordinary iteration are corrected step by step, until the continuation of the process is rendered superfluous. Errors can easily be detected, and if they are overlooked they retard the solution to be sure, but they do not render the calculations worthless, as is the case with other methods. For equations arising in statics, the cycles of repetition will rarely exceed five or six. The method is simple and easy to apply; and, its range of application is wider.

With regard to the examples chosen by the author, it may be pointed out that the simultaneous equations of Example 1 could be solved equally well, if not better, by the method of successive elimination of unknowns, using an ordinary 10-in. slide-rule. Such cases are rather rare in practical problems.

In conclusion, it may be stated that the method of converging increments is interesting no doubt, but it cannot replace ordinary iteration, as far as problems in statics are concerned.

L. E. GRINTER,[10] M. AM. SOC. C. E. (by letter).—This paper seems to bring into usable form a general method of solving simultaneous equations in structural analysis. Professor Dell sees very clearly the advantage of standardizing such solutions with the objective of eliminating errors and of shortening the labor involved.

The most interesting part of the paper, in the writer's opinion, is centered around the solution given in Fig. 4. The author likens this solution to the method of balancing moments, but actually the correspondence seems to be no deeper than a mere similarity of appearance. There is an interesting comparison of the basic conceptions involved that seems important enough to mention.

Within recent years there have been two quite different systems of analysis of indeterminate structures: (1) The classical methods dependent upon the mathematical solution of simultaneous equations; and (2) the modern methods dependent upon a physical picture of the action of the structure that can be expressed as a series convergence of moments and shears, or of angles and deflections. The two systems seem distinct and separate. Certainly the development of the modern methods, started by Hardy Cross, M. Am. Soc. C. E., occurred as a sharp cleavage from the mathematical procedure of the classical methods. Neither moment distribution nor the method of balancing angle changes was developed as a mathematical tool for solving a group of simultaneous equations. Each was developed as a physical procedure that gave rise to a solution of the problem without reference to simultaneous equations.

The calculations of Fig. 4 seem to fit in between the classical and the modern methods of analysis. It is strange that their presentation should follow rather than precede the presentation of the modern methods themselves. This merely illustrates what a distinct advance the procedure of balancing moments represented. In one tremendous sweep the classical methods were pushed aside and the modern methods were introduced. There was no intermediate step such as Fig. 4 might have represented.

Fig. 4, however, does not reveal a very clear physical picture for the computations recorded thereon. Equation (1) expresses as its right-hand member the important quantities used in Fig. 4. That is, the expression $\frac{6\,\bar{x}_1\,A_1\,K_2}{L_1^2} + \frac{6\,\bar{x}_2\,A_2\,K_1}{L_2^2}$ gives rise to the quantities recorded at the top of each column of numerals in Fig. 4; but this expression is actually equal to $6\,(\theta_1 + \theta_2)\,K_1\,K_2$, in which θ_1 and θ_2 are adjacent end slopes of the simple spans meeting at the joint considered. Thus, the quantity to be used in balancing is neither a moment nor an angle; it is the sum of two angles multiplied by the product of two stiffness factors. It does not seem hopeful to attempt to attach a very useful physical significance to such a quantity as this.

---

[10] Dean, Graduate Div., and Director of Civ. Eng., Armour Inst. of Technology, Chicago, Ill.

The argument as to whether the desirable solution of a given problem is mathematical or physical can never be settled. A purely mathematical solution such as the author suggests is useful to persons who visualize with difficulty. A physical procedure, which is merely doing with arithmetic what could be done to a model of the structure in the laboratory, is advantageous primarily to the person with imagination.

The writer sees the physical concept in analysis as being most useful when there is need for extension of the method to new cases, new arrangements or new structures. One can always "fall back" upon the fact that the arithmetical process merely states, step by step, the physical treatment that could be accorded a model of the structure in the laboratory. There is a one-to-one correspondence between the recorded arithmetical steps and the physical adjustments visualized for the model.

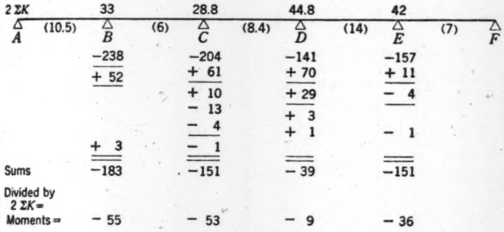

FIG. 6.—ABBREVIATED COMPUTATIONS OF $(\theta_1+\theta_2) K_1 K_2$

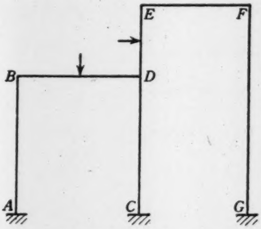

FIG. 7.—COMPLEX BENT

If the author is interested in saving time in analysis there is no reason why his calculations of Fig. 4 should not be reduced to those given in Fig. 6. In this form there will actually be fewer recorded intermediate results than would be used in balancing moments or angles, but an extension to a more complex case will not be self-evident. For example, if the problem is to analyze the bent of Fig. 7, what should be the initial factors at the joint *D*? Should the carry-over factors be the same as in Fig. 6, and how is the shear balance to be effected? These questions must be answered from a study of the simultaneous equations involved, and the answer is not self-evident.

The calculations of Fig. 6 have been simplified by a reduction of the number of significant figures and by a change of signs. Three significant figures obtainable from an ordinary slide-rule are, in the writer's experience, almost always adequate for design purposes. The results of Fig. 6 are expected to be in error by unity in the last figure, but the influence upon important moments is not significant. It is unlikely that the small moment of −9 at Point *D* would have any important influence upon the design. The change of sign for the carry-over values was adopted so that the column addition could be made for all recorded values and so that numbers need not be repeated. The result is a convenient and rapid automatic procedure for analyzing the special case of a continuous beam with simply supported ends. Whether it can be developed to be equally useful for other types of beams and for continuous frames is another matter. The author has performed a service by describing what might well have been an intermediate step between the classical and the modern methods of analysis although his actual procedure remains primarily a tool for use with the classical methods.

A. A. EREMIN,[11] Assoc. M. Am. Soc. C. E. (by letter).—The solution of equations with more than three unknowns is a complicated task even with the aid of a computing machine. It is gratifying, therefore, to encounter a simplified method, such as that presented by Mr. Dell, based on the principle of converging approximations. The computations may be still further simplified as demonstrated in Fig. 8, as applied to Equations (*B*) to (*E*) of the paper.

FIG. 8.—DISTRIBUTION OF BENDING MOMENTS

The stiffening factors in Fig. 8 are written in the same order as they appear in the equations. The carry-over factors were computed with stiffening factors at the joints and have logical directions. The distribution of fixed-end moments is made in a similar manner to that of the paper. The order of computations shown in Fig. 8 is easy to memorize and is in a convenient form, designed for greater assurance against errors of computation.

GEORGE H. DELL,[12] Assoc. M. Am. Soc. C. E. (by letter).—The method of converging increments, in a sense, is an iteration process. The term "successive substitutions" is more appropriate, perhaps, in describing the method preferred by Mr. Floris. It appears doubtful whether the occurrence of undetected errors is any less probable in that method than in the writer's. Regardless of the method used, all solutions should be checked, with a view to eliminating significant errors. If, in the method of converging increments, it is found that an error has occurred at some earlier stage of the solution, it may be eliminated conveniently by inserting the necessary correction at the point where the error occurred and carrying through the extended corrections, in red pencil, for a few lines.

* Including series summation at end of fourth set.

There is little or no advantage in finding the values of the unknowns before the solution has converged. The advantage in the method of successive substitutions lies, rather, in the fact that at each step the value of a given unknown is chosen in such a manner as to satisfy one of the original equations. However, unless the solution is thoroughly checked, errors will be just as likely and, frequently, as troublesome as in converging increments.

The computations in the method of successive substitutions may be arranged in almost precisely the same manner as in the method of converging increments. Those who prefer the former method will find this arrangement conducive to improved convenience, orderliness, and ease of checking. Table 6 shows such an arrangement of the first four sets of the solution of the equations in Example 3. The equations are written in vertical, or columnar, formation (Table 6(*a*)), as before (see Table 4). The first set of computations, Table 6(*b*), is exactly the same as in the method of converging increments. In the second set, Line 1, Table 6(*c*), the underlined term is $9.52 - (-0.06 - 78.12 - 6.96) = \underline{94.66}$, which is extended horizontally in the same manner as before. In Line 2(*c*), the underlined quantity is $-3.57 - (-6.96 + 6.76) = \underline{-3.37}$. In Lines 3(*c*) and 4(*c*), the underlined quantities are $48.00 - (-40.58) = \underline{88.58}$, and $4.02 - (-6.76 + 0.05) = \underline{10.73}$, respectively. The remaining sets are computed in a similar manner.

Mr. Floris states that the method of converging increments may result in a lengthy or divergent solution in some instances. The fact is that at any given stage in the solution the results are absolutely identical, whether by converging increments or by successive substitutions. He also states that the range of application of the latter method is greater. This is incorrect, for the reason just stated. On the contrary, the method of converging increments has a distinct advantage in the case of slowly converging equations which, after a few sets, acquire a uniform rate of convergence. To illustrate this fact, a comparison of the two methods of solution of the equations in Example 3 is given in Table 7. It will be observed that after twelve sets of successive substitutions (Table 7(*a*)), the errors in the unknowns are consistently in excess of 4%, while being of negligible magnitude after only four sets of converging increments and summation of series. It was precisely in order to gain this advantage that the writer chose to use increments, rather than the arrangement shown in Table 6.

In contrasting the mathematical processes of the older methods with the physical "pictures" of the Cross method, and variations thereof, Dean Grinter has presented a concise and extremely interesting discussion. His comparison is so complete and impartial as to make it difficult for one either to disagree with, or to add to, his observations. However, the writer believes that, fundamentally, the picture is the same in both classes of analysis, the principal difference being that, when equations are written, the physical conditions are built in, once and for all, whereas in the other type of solution, a single physical condition is satisfied at each step of the process. The solution is largely automatic in either case.

The form of solution used in Example 1 is readily extended to continuous beams with one or both of the end supports fixed against rotation. If, in Fig. 1, the left-hand support does not rotate, that fact is expressed by the equation

$$2\,M_0 + M_1 = -\frac{6\,A_1}{L_1}\left(1 - \frac{\bar{x}_1}{L_1}\right) \ldots\ldots\ldots\ldots\ldots (8a)$$

or, using fixed-end moments, with signs as previously defined,

$$2\,M_0 + M_1 = 2\,C_{01} + C_{10} \ldots\ldots\ldots\ldots\ldots\ldots (8b)$$

When included in a system composed largely of equations of the form shown by Equation (1), it is best to multiply both sides of Equation (8*a*) or (8*b*) by K_{01}. For the structure shown in Fig. 2, with Joints *A* and *F* fixed, the system of equations is as follows:

$$
\begin{aligned}
21\,M_A + 10.5\,M_B &= -\ 315\\
6\,M_A + 33\,M_B + 10.5\,M_C &= -\,2\,385\\
8.4\,M_B + 28.8\,M_C + 6\,M_D &= -\,2\,045\\
14\,M_C + 44.8\,M_D + 8.4\,M_E &= -\,1\,412\\
7\,M_D + 42\,M_E + 14\,M_F &= -\,1\,575\\
7\,M_E + 14\,M_F &= -\,472.5
\end{aligned}
$$

The corresponding alternate solution is then much the same as in Fig. 4.

The simplications suggested by Dean Grinter and Mr. Eremin for the form of solution shown in Fig. 4 constitute worth-while improvements. The former consists in changing the signs of quantities carried over and in indicating with a bar the fact that a distribution has been made at a certain point. The change of signs is advantageous in the "alternate" type of solution, but is not recommended in the tabular form of solution of equations. Mr. Eremin's improvement, Fig. 8, consists in showing the ratios in decimal form at the beginning of the solution, accompanied with arrows written in such a position as to be most helpful in making the distributions.

An interesting variation of the solution in Example 1 is obtained by dividing each equation by $2\,\Sigma K$. The resulting alternate solution will then be found to resemble closely a variation of moment-distribution which involves the "skipping" of joints. In this form, the denominators of the distribution ratios will be different on the two sides of a joint, and hence it would be doubly desirable to use Mr. Eremin's suggestion.

It does not appear feasible to apply the method of Example 1 to the type of structure shown by Dean Grinter in Fig. 7. For such a case, the method of Example 3, involving the solution of a system of equations expressing the necessary statical and geometrical relations, offers a convenient means of analysis.

The writer is deeply appreciative of the interest shown by the discussers of the paper and has derived considerable satisfaction in learning their various reactions. He considers them to be mainly favorable to the method presented for the solution of certain types of equations frequently encountered in structural analysis.

Note.—This Symposium was presented at the meeting of the Highway Division, Detroit, Mich., July 21, 1937, and published in June, 1938, *Proceedings*.

JOINT RESPONSIBILITY OF THE AUTOMOTIVE AND THE CIVIL ENGINEER

By C. F. Kettering,[1] M. Am. Soc. C. E.

Synopsis

A number of years ago the writer was making a motor trip in Kentucky running some tests, and had gone far off the main road. The map did not show any roads leading away from the place it was so small. It was late in the afternoon and he wanted to return home before dark. Driving along a little stream bed (which was the only road there was) he overtook an old gentleman driving a donkey hooked to a stone boat loaded with milk cans. Question: "Neighbor, what is the best way to go to Cincinnati from here?" Answer: "Go right up to the forks in the road. Now, it don't make much difference which fork you take but, to tell you the truth, Stranger, if I was going to Cincinnati I wouldn't start from here." Sometimes people get to thinking like the old Kentuckian; but they must first recognize that, whatever their destination, they must start from where they are.

The leaders of the automobile industry have never been able to predict what the industry will offer the public two years in advance. If they knew what the car of ten or twenty-five years in the future was going to be like they would be making it now. To afford some idea of what the future might bring without taking all the responsibility upon his own shoulders the writer asked a number of men, holding responsible positions in the automobile and allied industries. On some questions they were almost unanimous in agreement; on others, they had entirely opposite ideas. All the various prophecies and predictions made in the past have been studied and, with these, the writer has tried to present, in some kind of complete picture, the requirements that will be demanded of those who will supply roads for the automobile of 1960.

All one can do now is to determine conditions as they are to-day, what they were yesterday, and, by projecting a line through the two known points, reach some idea of what the future may hold. It is an excellent idea for the road builders and automobile makers to get together and exchange ideas concerning their mutual problems. After all, the vehicle and the road must form a complete transportation system. Each one is dependent upon the other for the success of the whole. Civil engineers have the most difficult job because of the time factor. They must build a road to last twenty or twenty-five years for vehicles whose average life is only seven or eight years. Before a road is

---

[1] Vice-Pres. and Director, Gen. Motors Corp.; Pres. and Director, Gen. Motors Research Corp., Detroit, Mich.

one-third used up, there is an entire new generation of motor vehicles with their new requirements; and before the road is finally ready for replacement the requirements have changed several times over. The aim of this paper is to predict what changes this time factor will demand so that civil engineers can build accordingly.

INTRODUCTION

The greatest problem involved in all thinking is to determine the time rate of action. The time rate of gravitation is known. If a man jumps from a window the time it will take for him to hit the sidewalk can be computed. There are other natural laws which are just as fundamental as the law of gravitation. Each of them has an entirely different time rate of action, and these are not understood at all.

An interesting incident occurred in connection with the salmon fishing industry in one of the large rivers of the United States. The industry was persuaded that it would be a good thing to have a salmon fish hatchery and, therefore, two or three of them were built. Fish hatching was begun, and the product sent out, to return again after the proper cycle. One year, one of the hatcheries burned down, and there was an immediate demand for a new one. People went to the authorities to get an emergency appropriation for building a new fish hatchery; but the time rate of political action is not that fast. The subject had to be discussed and the hatchery was not built that year. Some of the opponents argued, "they had just as big a run of salmon the year after the fire as they had the year before." The result of the delay in building was that, when the proper year in the cycle came around, the salmon catch was small because of the absence of the product of the hatchery. This has happened in some other problems, such as road building. Eight or ten years ago engineers missed something; so "the run is not so good" this year. This time factor must be studied so that similar troubles will not recur. Maybe the place to start is with the politicians.

The writer belongs to a group of men who believe the world is not finished. Nothing is constant but change. Men work day after day, not to finish things, but to make the future better. They want the future just as nice a place as they can make it because they will spend the remainder of their lives in the future.

Many things need to be torn down and thrown away. The country needs to be rebuilt and made better than ever before. The economists and bankers say, "Where are you going to get the money?" The money will come from the same source as when the country was built this far. There was no money with which to start. All that the people did was to dig each building out of the ground. It has always been here in the country, only in a different form.

Man-hours can be used to convert material into anything that Man needs. An intelligent people will supply the work. When materials are converted into human utilities money is only used as conveyor to carry it from one point to another. Sometimes, people calculate entirely too much in dollars. The wealth of the nation is not in dollars; it is in useful products. The positive side of economics is the movement of useful material through the channels of trade. That must always precede the return flow of money through the counting houses.

In preparing this paper the writer sent a list of eighteen questions involving factors that might affect road requirements in 1950 or 1970 to many people who it was thought might have valuable information on at least some of them. Their opinions were requested on any particular one subject upon which they had information; or, if they wished, they could comment on all eighteen. The subjects upon which the questions were based were:

(1) Growth in registration of passenger cars.
(2) Growth in registration, use, etc., of trucks.
    (*a*) Will railroads pick up and deliver less than car-load lots?
(3) Growth in registration and use of buses.
    (*a*) Will buses supersede street cars in cities?
(4) Effect of the trailer on automobile design, roads, laws, traveling habits, trailer camps, home building, population movement, etc.
(5) Road speeds of passenger cars, trucks, and buses.
(6) Size and weight of road vehicles.
    (*a*) Will this make segregation of different types of traffic necessary?
(7) The future of other types of motive power, such as the Diesel engine and the problem of suitable fuels.
(8) Design changes in the automobile which will affect road-building requirements and make safer vehicles.
(9) Lighting on the vehicle and highway.
(10) The future of tires—changes in coefficient of friction, life, etc.
(11) Possibility of high-speed trunk highways and separate truck highways between cities.
(12) Will travel be overhead or underground in congested areas?
(13) Will the population live in larger cities or will the trend be back to smaller communities?
(14) What mechanical devices are practical to control traffic conditions and actions of the driver?
(15) How will parking in cities be solved?
(16) How will laws regulating traffic, vehicles, and the driver affect road requirements?
(17) Type, kind, and number of highways that should be provided for the future.
(18) Possibility of chemistry contributing better road materials or treatment.

INCREASE IN REGISTRATIONS

The probable growth in population in the United States for the next 25 yr is quite easy to predict and such predictions have proved reliable in the past.

In Fig. 1, Curve (1) shows the population growth from 1900 to 1930, as taken from reports of the United States Census Bureau. From 1930 to 1960 the probable future population is shown as estimated by the American Petroleum Institute. The data represent the averages of five estimates from life insurance companies and others. Passenger-car registrations are plotted as Curve (2) with the estimated increase per 5-yr period to 1960. The estimated number of persons per car is plotted as Curve (3). Registrations in trucks are estimated to increase to 6 000 000 by 1960 (see Curve (4)). Curve (5), Fig. 1, shows the total estimated motor-vehicle registration by 1960 as more than 37 000 000 vehicles. The registration values were estimated by the American Petroleum Institute.

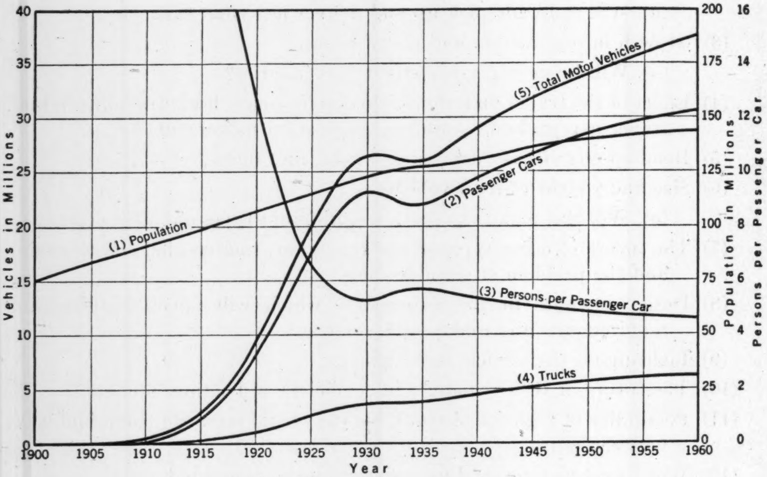

FIG. 1.—ESTIMATED MOTOR VEHICLE REGISTRATION TO 1960

From the foregoing it is apparent that engineers will have to provide roads for 50% more motor vehicles in the next 23 yr. Since many main roads are already inadequate to carry the traffic safely, it would seem that a tremendous task lies ahead. The area of the various countries per mile of road, and the number of cars per mile of highway, are as follows:

Nation	Area, in square miles per mile of road	Cars per mile of road
United States	1.0	8.2
Germany	0.8	4.4
France	0.5	4.9
Great Britain	0.5	10.3
Italy	1.1	3.6
Australia	6.3	1.3
Brazil	35.2	1.3

In comparison with most of the remainder of the world, highways in the United States are now congested. An increase in registration on the present system would almost prohibit much of the usual driving. What the optimum ratios should be is not known, but it is certain that more improved highways are badly needed.

Almost all those who answered the questionnaire believe that the population trend is away from congested areas. Railroads, unsupplemented by efficient highway transport, caused concentration of population at station points. Automobile transportation counters the railroad influence, and provides economic and social communication facilities, at greater distances from, and independent of, rails. Man has an inborn feeling for open spaces and a plot of ground, which he cannot lose entirely. There are a number of indications that the trend is away from cities and back to smaller communities. Several large manufacturers have definitely committed themselves to a policy of erecting new plants in small towns. One of the largest retail companies, with stores all over the country, is opening or building new stores only where large parking spaces can be obtained for the use of its customers. Traffic congestion and the problem of parking will have the greatest influence on this movement. A number of men think cities will be necessary for conducting many forms of business and government, but that a large percentage of the population can live more comfortably and find most of their needs cared for in small communities.

There are those who predict the "string" or "ribbon" city. This is an almost continuous population existing on both sides of a trunk highway. The ribbon city may be pictured as an elongated community like a long string with beads of different sizes strung upon it more or less erratically. The biggest beads are the large centers of population. They are certain to develop because of the need of centralizing large financial institutions, railway centers, ports, costly public facilities, such as water-works, gas-works, museums, libraries, and other agencies which have grown with large cities. Small "beads" will develop at strategic points and will consist of all gradations between the large city and the equivalent of small country cross-roads.

Others believe in the increase in importance and number of small communities which would be supported by a local industry. Each town would have at least one factory. Because of the greater amount of leisure which every one has, residents of small cities would be able to have plots of ground for cultivation and would raise part of their food requirements. This would make them less dependent upon manufacturing for their living. This type of rural life would make highways doubly important, both for pleasure and commercial use.

There are others who believe that faster means of transportation from outside into the center of large cities is coming. Workmen could live distances as great as fifty miles from their work. Homes would be situated on large plots in the open country. The city would be for work, business, and commerce. To accomplish this would require high-speed, limited-access trunk highways to the city limits. The city would have to have many elevated or depressed highways crossing it in every direction. Present level streets would be used for local travel. Local conditions will govern whether the thoroughfares are built underground or overhead.

PARKING

City parking is one of the most serious problems. It is inconceivable that motor-car owners will long continue to park cars almost bumper to bumper along busy city streets and suffer the damage and inconvenience which result. The traffic capacity of the present city street system could be almost doubled by eliminating parking and using the streets for travel only, as they should be used.

Experience seems to indicate that drivers and store owners have unconsciously, but effectively, accepted the idea that cities must provide the parking space required for the ordinary transactions of business and pleasurable pursuits of their citizens. The only regret in the mind of the average person seems to be that he has not been able to find any method of placing more than two curbs along a given street. The people in Detroit, Mich., have even found a way to do that on a few streets.

Accepting the idea that cities must provide space, it would seem far cheaper for them to provide parking lots than to supply expensively improved streets for parking purposes. If it is right for a city to go so far as to condemn and acquire strips from the front of existing lots, and even buildings, to convert these strips into additional highway widths, to pave them expensively, and then to have large parts occupied permanently for parking, why is it not legitimate and much more logical to condemn cheap but well-located property for conversion into city-operated parking lots?

In residential areas there is a grass plot between the sidewalk and the street. Why should not this space be used for parking instead of the traffic area of a street built for heavy duty? There are even city ordinances prohibiting such a practice.

Parking garages, either separate or located within the building they are meant to serve, are growing in number. Every large building should provide adequate parking space for its tenants and customers. Several well developed means of doing this are in use. Double-decked or triple-decked exposed parking lots may be necessary in some areas. However, the problem of parking is not one for either the automotive engineer or the civil engineer to solve directly.

PASSENGER CARS

What possible changes in the passenger automobile might affect road requirements? The car has, in no way, reached a state of standardization and there is no indication that it will. The car of ten or twenty-five years from now (1938) will be just as different and will have just as many improvements as they have had in the past ten or twenty-five years. The 1937 car will certainly seem as antiquated to those who see it in 1960 as the 1912 car does now. It is the policy of the automobile industry to improve its product constantly.

Sometimes an idea of the future may be gained by looking at the past. Suppose a buyer had picked out a brand new 1912 car just as it came from the production line. At that time every one agreed that it was the best car that could be obtained. Suppose it was sealed in an air-tight glass case and the price ($2 000) marked in gold letters where every one could see. As the years passed the buyer went back to look over his perfect car. The second year, its value had decreased to $1 800; and, as each year passed, its value decreased until in a short time (much less than the twenty-five years since it was sealed up) only the junk man would value it. Why? Remember it was sealed so that nothing could happen to it—no rust or corrosion, and no wear. The car remained exactly as on the day it was purchased; but what changes there have been since 1912 in the idea as to what an automobile should be! Cars now have self-starters, four-wheel brakes, better finishes, higher performance, improved appearance, fine riding qualities, and many more attributes than any one could mention. If a buyer were to do the same with a 1937 car now, he would surely have the same experience in 1960.

It is not possible to foretell exactly what the car of the future will be like. There are so many factors that might enter at any time to throw such prophecies out of line. It is feasible, however, to discuss some of the problems automobile engineers are talking about and experimenting with; questions they think important enough on which to put time and effort. The requirements for maneuvering and controlling the car, for example, are closely related to road conditions in many instances. These items are affected by such factors as steering, "hill climb," top speed, vision, lighting, riding quality, and ease of control, all of which are directly concerned with the safe use of the roads.

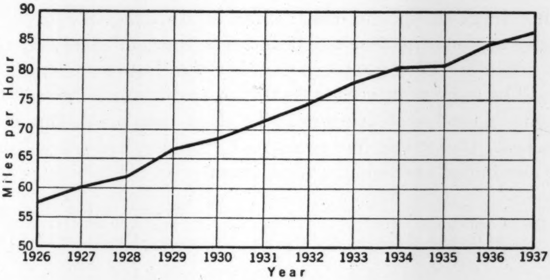

FIG. 2—CURVE OF MAXIMUM SPEED

Engineers do not always think of engine design as having anything to do directly with road building and safety and yet the power source may profoundly affect the type of surface upon which the car rides. It influences performance factors: Speed, acceleration, economy, flexibility, and "hill climb." From several sources of information one learns that there are indications that the practical usable maximum speed has been reached and that engineering emphasis will be placed on other factors in the future. Customer research surveys have shown that people, on the average, do not want to travel much faster than 60 miles per hr; but they want to go that fast without effort. Certainly, roads should not be designed for any less than 60 miles per hr. Other authoritative sources of information reveal that speed is an inherent reason for the widespread use of the automobile and that designers should do everything possible to maintain that advantage. As roads and cars become better, speeds may increase still further and with more safety than at present. Fig. 2 shows the trend in maximum speed of a representative group of cars for the eleven years, 1926–1937.

Although the question of maximum top speed may be controversial and may depend upon how safe the highways are made, every one insists that a higher average speed should be maintained between cities. This indicates the need for high-speed highways built to carry traffic safely. Elimination of grade crossings, limited access, separate lanes, and locations to pass around cities, are some of the requirements. These highways are necessary between main centers now, and their requirements will not depend upon changes in the vehicle that may be anticipated at the present time.

Acceleration and "hill climb" are closely akin. Accelerations will probably increase. This ability is important in "getting away" from a stop and increasing to traffic speed, to pass and return into line in a short distance, and to cross intersections without delay. It will affect the timing of traffic lights and regulating devices. It now appears that any passenger car will be able to negotiate a 10% grade without losing its speed. Undoubtedly, the trend is for the performance of trucks and buses to equal more nearly that of passenger cars. This will undoubtedly be true in the future.

The ability to stop is of major importance. Here is a problem that civil, as well as automotive, engineers can do much to solve. For its part the automobile industry will offer better and better brake equipment as it learns more and more how to do the job. However, the coefficient of friction between road and tire will always be the limiting factor in stopping distances. Although something may be done with the tire to increase the coefficient, the road surface itself seems to offer the greatest possibility for improvement. Everything possible should be done to increase this factor, and it might be well to include a minimum limit in road specifications. To show how much this may vary on different surfaces, the writer has computed stopping distances from 50 miles per hr for a number of coefficients, as follows:

Coefficients of friction	Distance, in feet, required to stop from a speed of 50 miles per hr
1.0	83
0.9	91
0.6	140
0.4	208
0.2	416

The large variations are clearly shown. Surfaces and materials vary the friction characteristics greatly and warrant important consideration in building new roads. The change with weather conditions also is of great importance. There is little that can be done with the tire to give higher values compared to the large variations encountered on present-day roads. At present, a coefficient of about 0.6 is all that can be relied upon in designing brakes.

The size of passenger cars will be determined largely by the space required to house the passengers. Probably this will not change very much. Road clearances of a little less than 8 in. have been common for a number of years and it would seem that nothing now being developed would reduce this value. Clearances are important in building alley intersections, intersection street grades, and driveways. Lower door clearances, apparently, are here to stay and must be taken into account in constructing curbs. The height of the center of gravity has a bearing on the capability of the car to "hold the road." For a number of years it has been about 24 in. above the road. Any lowering would only slightly affect roads. Turning radius is important only in parking. This value has averaged about 26 ft for some years.

What will be the effect of the engine in the rear? This subject seems to be much before the public at present. There are some good reasons why this design would be desirable and some, equally good, why it might not prove so feasible in production. A rear-engined car would provide better visibility with clear vision directly ahead. It would probably eliminate much engine noise, heat, and odors, and allow lower floor-boards. However, maneuvering, particularly around a corner, requires an almost equal distribution of weight on the front and rear wheels. To accomplish this in a rear-engined car of reasonable wheel-base will require an engine of about one-half the weight of the present units. The rear-engined car with acceptable handling characteristics must await power plant and drive developments. Even with a rear-engined car, road requirements would not be changed materially unless accompanied by radical changes in performance.

The rubber tire is one of the most important factors that made the present automobile possible. It is interesting to note that Mr. Dunlop was not thinking of automobiles at all when he developed the pneumatic tire. He undertook to make a better tire for his son's bicycle. He took a wheel and put a canvas over it, and inside inserted a rubber tube blown up by a football pump. That was the beginning of the pneumatic tire. Finally, an unknown bicycle racer beat a champion because he used pneumatic tires and the bicycle trade took them up. When the automobile came along the tire was ready.

Tire mileages have increased from less than 1 000 in the early days until now (1938) a tire will last for more than 20 000 or 30 000 miles and the owner objects if he does not get that many. One place where tires may be greatly improved is in blow-out resistance. At one proving ground tires have often been blown out with dynamite caps at speeds of 70 miles per hr or more without hurting any one. In fact, motion pictures taken by a following car and aimed at the tire show only a slight sidewise movement when the tire burst. Such procedure is not recommended, of course, as serious accidents can be caused by blow-outs, especially in front tires.

The trend in tire development is toward improvements in compounding technique that will result in more heat-resisting rubber compounds. A new tire is being produced which has a strong rayon cord that maintains its strength at a high temperature. More than 20 000 tires have been produced and 500 000 000 miles of wear imposed on them to be sure that the development is a sound one. The outstanding characteristic of this tire is its freedom from carcass failure and blow-outs, particularly where trucks and buses are operated at high speeds and under heavy loads. One company cited tests by which these new tires outlasted the specially constructed test cars themselves in runs at 120 miles per hr over the salt beds of Utah. It seems that the tire chemist has scored again and motorists will not be limited in road speed by tire weaknesses.

MECHANICAL DEVICES TO CONTROL CARS

It is not difficult to conceive of mechanical devices on roads and highways that might act to reduce the accident rate. Photo-electric cells, relays, and mechanical devices have been proposed for stopping cars automatically. This could be done in a practical manner just as is now done on railway trains. It is doubtful, however, whether engineers could justify the expense and difficulties of enforcement in the use of such devices.

For several years there has been a presistent clamor for governors on all motor vehicles. Speed is claimed to be the cause of most of the accidents. However, the public would not allow the designer to govern the speed to less than 50 miles per hr. Only a very small percentage of accidents happen at greater speeds. Limiting the speed to 50 miles per hr would not affect accidents in the city, where maximum speeds seldom reach this value; and it would only prevent a few accidents on the open highway. Many surveys have shown that the average speed is less than 45 miles per hr on good roads and only a small proportion of cars travel as fast as 60 miles per hr.

Automatic devices that limit speed or take the control away from the driver may be the cause of accidents. It is often necessary to accelerate rapidly to cross an intersection, pass around a car and back into line, or enter traffic and increase the speed to avoid trouble.

LIGHTING—ROAD OR VEHICLE?

Authorities agree on one fact: Night-driving conditions are far behind day-time conditions, and for one reason—lack of adequate lighting and glaring headlights. Many studies have been made on the relative accident rates between day and night driving. Most authorities agree that night driving is three or four times more hazardous than day-time driving. The future must avoid this condition. Here is a problem which both groups—the automobile industry and road builders—will have to solve individually. It seems logical that many miles of congested highways, especially between large centers of population, could be lighted economically. The first cost and the upkeep are high; and, with any electrical equipment now in prospect, these items make it impractical to light all highways. It has been estimated that the upkeep alone of the lighting for roads in the United States would cost more than the total annual expenditure for roads in the entire nation.

However, the writer would like to outline what has been done in the past generation in lights for other purposes. The present tungsten incandescent lamp is about eight times more efficient than the original Edison carbon lamps. The new sodium vapor lights are said to give nearly three times as much illumination as the best tungsten lamps. It does not take a very good prophet to guess that this progress will not stop. The future will certainly see vast improvements in methods of producing light with small expenditures of power. Entirely new methods will surely be found for producing light without the great heat loss which now must be accepted. The firefly, deep sea fish, and other of Nature's means of producing light can teach engineers an entirely new technique. Already, a few unrelated facts are known which may prove to be the starting point for large lighting industries. In a demonstration which the writer has often given, he pours two liquid chemical compounds together. Each is almost water-white and inert. When they are mixed, they create a pale blue light, strong enough to permit reading a newspaper in the dark, which persists for several hours. What this means for the future is difficult to say, but it is well known that many of the greatest industries are founded upon scientific facts as simple as this one.

For some time to come it seems likely that illumination on most roads will be supplied by the automobile itself. The problem is to obtain good vision without glare; and this the automobile engineer is working on all the time. From the crude oil lamps of twenty-five years ago the modern car has now progressed to fairly effective electric lights with several beams to suit varied conditions. This lighting can be improved still further, but how to do it is the problem. Since 1918, experimenters have tested thousands of means of eliminating glare, which would still provide adequate road illumination for the fast-driving pace most owners demand.

Only one solution has received widespread attention; that is, the use of polarized light. At first, this may seem to be the answer to the question, but there are still many problems to be solved before it can be utilized on a car. In this system a beam of polarized light is projected upon the road by a headlight which has a polarizing screen in front of the light bulb. The oncoming driver views the road through a screen in the windshield, or special glasses which have a polarizing screen set at right angles to that of the headlight of the oncoming car. Therefore, he sees only a small percentage of the light from the oncoming car, but the light from his own lights is little affected by the viewing screen. Glare is practically eliminated without much reduction in road illumination. The objection to the use of polarized light is that it requires about four to eight times the candle-power light of present systems to give the same visibility. To be effective, it would have to be fitted to all cars. The expense of the screens themselves is high, although this would undoubtedly be reduced with more experience in manufacturing.

Other systems have been proposed for providing adequate road illumination and, at the same time, eliminating glare from oncoming cars, such as a system of colored lights. Every car would be equipped with headlights capable of producing a beam of either one of two colors, together with viewing screens of these colors. Suppose the two colors were blue and orange-red. Cars traveling north and east, for instance, might be required to illuminate the road with the blue light and would use their blue viewing screen. Cars traveling south and west would use the orange-red light and screens. The colors would be selected so that the blue screen would transmit none of the orange-red and the orange-red screen would transmit none of the blue light. This would eliminate glare from oncoming cars although it appears that the efficiency of the system would be low.

A problem in road research closely akin to illumination is road color, and brightness, and their effect upon visibility, both day and night. This is probably one of the minor considerations in selecting road materials and yet it should be given some consideration. The related problem of visibility, front and rear, from the driver's seat is an important subject which has commanded increased interest, and should lead to much better visibility in the future. Narrower front pillars, better seat positions, glass angles, and locations to eliminate reflections, sun-glare shields, front-end shape, and many other considerations are involved. From the standpoint of the road, good highways signs, elimination of blind corners, location of signal lights, center lines and markers, and road color are problems of importance to the driver, especially when he drives over a new route.

BUSES AND TRUCKS

There will be a great expansion in the use of trucks and buses in the future. From the road-builders' standpoint the size and weight of the vehicle will be important. Almost every one agrees that this factor will be settled by law and that maximum sizes and weights will not exceed present limits. The trend seems to be toward many more smaller, faster, more mobile units.

There will be a tremendous growth in the use of buses, especially to replace street cars. Although buses cannot supplant street cars entirely, in all cities, it appears that there is a certain population below which buses can take their place. It has been estimated that this size is between 100 000 and 200 000. For large cities, and particularly in cities in which there are arterial highways, the street car will remain the backbone of the transportation system.

The records show how rapidly the public has accepted the motor bus in cities and, in the final analysis, their wants will always control. In 1922, only 18 cities depended exclusively on motor coaches for transportation. Within a period of 10 yr, 300 cities were using buses exclusively. To-day (1938) the number is well over 420. During the past five years 75% of equipment bought by city operators has been gasoline buses.

For inter-city use the bus has shown similar strides forward in the twenty-five years, 1913–1938. Passenger service is supplied by buses in 48 500 communities in America which are not served by rail lines and are totally dependent on highway transportation. These are the modern "lost Provinces" which have again been discovered by highway transportation. In several mid-western States, from 20% to 40% of the communities come under the heading of "Lost Provinces."

The public has "sold" itself on the value of buses, and their speed, economy, and convenient schedules. Comfort, appearance, speed, acceleration, "hill climb," and safety have shown marked improvement in the past few years and the limit has not been reached in these factors. The trend has been toward large units, seating more than thirty passengers, but of considerably lighter weight than those of the past. Aluminum and pressed steel reduced the weight of one large bus by 6 000 lb and with an increase in structural strength. The motor bus has definitely found a place in the transportation system of the United States and will have to be provided for in any future highway program.

Statements that the truck will eventually drive the railroads out of business can only come from those not acquainted with the problems of trucking. A "long haul" in truck language means a "short haul" in railroad language. At present, the truck is usually not economical for distances greater than 250 miles, or for other than the higher grades of freight. There is plenty of business for both the truck and the railroad.

Railroads, themselves, are using trucks in ever-increasing numbers. Door-to-door delivery has been tried sufficiently to show its value and this service will expand in the future. For short hauls there will be more trucks of every kind, their maximum size being limited by laws and regulations.

The possibility of separate highways for commercial vehicles presents many problems, most important of which, perhaps, is the cost. In most instances, the commercial development that has come in the wake of motor transportation has been along the present highways. Even if separate truck highways were constructed, it would still be necessary for trucks and buses to use present highways to serve the industries and business places along them. If separate highways are necessary, in some places, perhaps they should be constructed for passenger cars and leave trucks where they are. Trucks could be kept off the special highway for the passenger cars, but they cannot be kept off the present highways regardless of the construction of other truck highways.

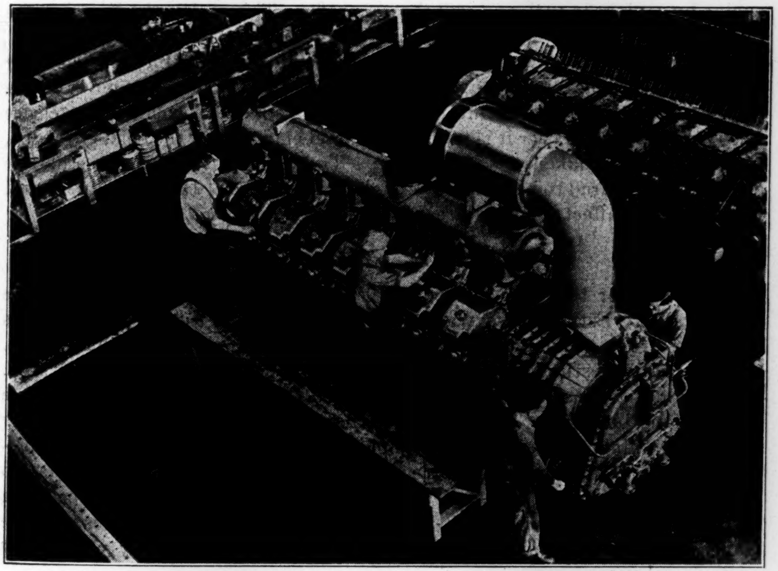

FIG. 3.—A MODERN TWO-CYCLE DIESEL ENGINE

DIESEL ENGINES FOR MOTOR VEHICLES

The Diesel engine is not new; it has been in use for more than forty years. Until given wide publicity by its use on the streamlined trains, it was little known by the public. Now, many car owners are talking Diesel engines as if they would displace the gasoline engine entirely in motor-vehicle transportation.

The Diesel is a remarkable engine for some purposes. It is the answer to many of the problems the railroad companies have been trying to solve for years. Passenger trains have been able to maintain faster schedules than they ever thought possible at a great saving in operation and fuel cost. Full-length trains have reached speeds exceeding 120 miles per hr. Time for upkeep in the roundhouse has been reduced one-half. Water is not a problem in dry, alkali areas because the loss of cooling water is negligible.

The Diesel engine is here to stay and will soon be common in large motor vehicles. Cross-country trucks and buses can now be obtained with Diesel engines and the future should show an increasing use of this economical form of power plant. The statement that they save one-half the fuel cost needs some explaining. One of the largest existing fleets of motor vehicles has a yearly gasoline bill of more than $2 000 000. To save one-half of that sum would be well worth while; but to do so, it would be necessary to spend more on the original equipment. It costs considerably more to make the Diesel engine, principally because of the expensive fuel injection system. By driving enough miles in a year, it may be possible to pay the extra first cost of the engine by savings in fuel, and still show a profit. This makes the Diesel engine possible in commercial vehicles, but not necessarily for passenger cars.

The main reason, however, why Diesel engines are not built in passenger cars is that no one knows how to build them. The writer has never seen a successful Diesel engine in automobile cylinder sizes. The larger the engine size (see Fig. 3) the easier it is to make a Diesel engine; and the smaller the size, the easier it is to make a gasoline engine. Truck and bus Diesels are still large engines as compared to passenger car engines. The use of Diesel engines should not materially affect road requirements in any event.

Trailers and Mobile Homes

A new factor that has entered the "picture" in the last few years is the house-trailer. Estimates vary as to the number now on the road, but it seems that there are several hundred thousand trailers, housing several million people. A conservative estimate is that 100 000 new ones were produced in 1937. These values are insignificant when compared to the 26 000 000 motor-vehicle registrations, but it must be remembered that trailer construction as an industry is just beginning. What the future holds, no one is sure. Opinions and prophecies vary from those by people who think that trailers are just a fad to those who predict that one-half the population of the country will be living in trailers within twenty years. There may be too much optimism in the trailer industry itself; and yet it has almost doubled itself every year for the past several years.

More than ten years ago (1926) the writer had some experience with living a trailer life. A stock bus was fitted out for living purposes and a party of seven took an 8 000-mile trip through the West. Traveling was surprisingly comfortable, and the accommodations, in many cases, were better than could be obtained in the country through which the party traveled. The present trailer is much better equipped and can find better parking places than it could ten years ago.

There are those who predict that the trailer will grow into a mobile modern home of several rooms, a home that can be moved when the head of the family changes locations of work. There are now several designs of expansible trailers which make three-room or four-room bungalows complete with all modern conveniences. They visualize a working population housed in these mobile homes, which can be moved from place to place as working conditions change. The owners would rent small plots of ground on the outskirts of industrial areas, where they could raise their own food, be out in the open country, and use the car for transportation to and from work. They would have all the benefits of owning their own home in the country, but would not be tied down because of high mortages or ownership of stationary property. Land could be rented from farmers and a new type of community life developed. After one studies some of the plans of these mobile homes, it becomes apparent that there are possibilities in this field, especially when it is realized that 80% to 85% of the present trailers are bought by working men for permanent homes.

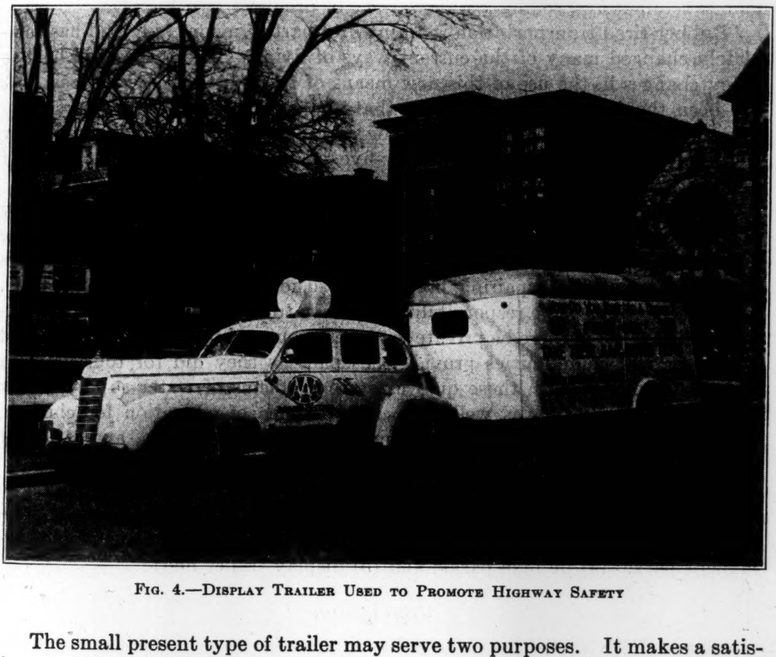

FIG. 4.—DISPLAY TRAILER USED TO PROMOTE HIGHWAY SAFETY

The small present type of trailer may serve two purposes. It makes a satisfactory temporary dwelling for vacations and it can be used as a sample display room for commercial products. With the trend definitely toward more leisure and earlier retirement of men in business, it is certain that some effect will be felt in the modern way of living. The trailer is one answer to those who retire on a modest income or who depend upon the Social Security Act for a living.

Already a number of businesses use trailers for commercial purposes. Almost every one can remember the old days when commercial salesmen, or "drummers," traveled their territories by horse and buggy or by train. Then, along came the automobile, and they could cover as much territory in a day as they could before in a week. Now another change is appearing in methods of selling—the display trailer. It is doubtful whether any one conversant with the problems of commercial selling will gainsay the advantages of display trailers as an effective tool in the hands of the salesman. To bring an alluring show window to the prospective buyer has been the ideal of many a sales manager. This is exactly what the display trailer is accomplishing. The adoption of the house-trailer to display use is certain to have some far-reaching effects on sales methods.

At present, the varied products being displayed in trailers range from medicines for pre-natal care, and obstetrical instruments, to caskets and religious instructions. Such vehicles have the advantage of full-line displays, privacy, mobility, and spot delivery of small articles. They may become mobile retail stores, selling a wide variety of products (see Fig. 4).

Rubber-tired transportation is an integral part of modern life and has completely changed many of the current ways of living. The future will hold as many changes in the use of this new means of transportation as the past. It has been the experience of the past that the second twenty-five years of an industry always shows the greatest progress. The motor-car industry is only well under way on its second twenty-five years. It will make more use of highway transportation as better, and more adequate, roads are provided.

Assuming that the trailer is here to stay and that its production is only in its infancy as an industry, road requirements will be changed to supply these new needs. Highways will have to be wider, with wider bridges. Many more turn-outs for parking, repairing, preparing roadside meals, and feeding the baby, will be necessary. The responsibility will have to be fixed for over-night parking facilities. Will there be private ventures promoted by gasoline stations and others, or will communities provide the space as they did for tourists using tents? Combined with these questions are problems of water supply, power outlets, and sanitation as well as social problems of education for children, taxation, effect upon the birth rate, police and fire protection, and a host of others.

It appears that trailer camps will fall into five general classes, according to the use to which they will be put. These uses can be listed as follows: (1) Stop-over camps; (2) vacation or recreational parks; (3) semi-permanent and permanent parks; (4) de luxe parks; and (5) display trailer marts.

CONCLUSION

The highway of the future must be as different from the present highway as the automobile of the future will be from the present automobile. One thing is certain; the future will demand change. As an automotive engineer, the writer does not know how the civil engineer will accomplish his results. There will be (in fact, there are now) certain fundamental requirements that have not always been incorporated in roads: The best road for the automobile will have the least obstructions to the steady flow of traffic. Whether this means limited-access "free ways," such as Germany is building in its Reichsautobahnen, is difficult to state. Neither can one state definitely whether the engineer should build elevated highways, longer curves, wider roads, underground highways, more grade separations, better surfaces, or create new road materials, to solve the problems. Civil engineers are in a much better position to make surveys and to design roads than automotive engineers could ever be, if they are given the opportunity.

Neither group is suffering from a lack of information on how to handle the problem. Any expert could design and build a suitable safe road to connect two cities, or to cross a large urban area, if he were given the job to do it as he really thought it should be done; but there are too many other than straight engineering problems with which to contend. Probably one of the greatest problems is to prevent diversion of tax money collected for roads into other channels. The money collected for roads should be used for that purpose and not for building city halls, jails, and other projects. To concentrate on the worst of problems: First, solve the means of handling traffic on the most congested routes; and then build the main streets to handle their traffic faster and with greater safety. Instead of trying to solve all problems at once, solve the most pressing ones first. If this is done in a systematic manner, the highway system in the United States will be the best in the world within a few years.

Men in the automobile industry believe that a highway system, should be based on traffic surveys to determine requirements for the types of roads designed to carry traffic safely. Such a plan would require a primary system of high-speed highways crossing the country in all directions. It is estimated that about 50 000 to 60 000 miles of such super-highways would be sufficient. Leading from these would be a secondary system of good highways serving small cities and towns. The third system would consist of land service highways serving rural areas. In addition, a similar system is needed, in miniature, to carry the traffic in large cities.

The best type of road should embody all the knowledge the highway engineer has at his command for building a safe roadway to carry motor vehicles at a reasonably high speed. Where it is necessary, it should be above or below the ground. In any event, it should be a limited-access "free way" designed for the one purpose of carrying traffic smoothly. Where roads do lead into it, they should be provided with accelerating lanes so that traffic will not be interrupted by new vehicles entering from the side. Everything should be done to make for a free, uninterrupted flow of traffic. Crossings should be eliminated, curves should be banked, long-sight distances should be provided, bridges should be wide, and all "bottle necks" eliminated. Traffic lanes should be separated to prevent "side swipes" and head-on collisions. Surfaces should be non-skid. Where it is necessary, adequate signals and signs should be installed. The entire system should be governed by a uniform set of traffic regulations made to fit the new conditions.

This entire highway system should be paid for by the motorist. However, all the money collected from him in taxes should be used for this purpose. The automobile owner pays more than $1 000 000 000 per yr in taxes without much complaint as long as he knows his money is going for good roads. In some years almost one-fourth of his money has been diverted, directly or indirectly, to other uses. This "rifling" of the road funds must stop if the United States is ever to have an adequate highway system.

THE TREND OF MODERN HIGHWAYS

BY THOMAS H. MACDONALD,[2] ESQ.

SYNOPSIS

Highway construction and use are undergoing changes that are relatively slow but none the less sure and continuous. Changes in motor vehicles, in the sources and amounts of highway revenue, and technical advances in road-building methods, are some of the more important factors that will influence future highway trends.

Scientific highway planning and administration are necessary to provide highways to serve urban and rural needs with the road-user taxes that can be made available. Factual data are being provided that will permit the scientific planning of State-wide and nation-wide systems. This is the outstanding trend in the highway field.

Stabilization of soils to produce foundations of predictable behavior, elimination of intersections at grade with railroads and other highways, and provision of facilities for free flow of traffic from congested to suburban areas, will be important parts of future work.

An important beginning has been made in construction of super-highways and such work will be continued. Present policies indicate that their location will be integrated with population centers, and that the layout will not be on the transcontinental basis.

INTRODUCTION

Any attempt to reach far into the future of highway development invades a speculative field if limited to isolated examples of the unusual. However, if taken as a whole, each of the major public undertakings changes slowly in character through definite causes. These changes, if relatively slow, are none the less sure and continuous, depending upon the rate of progress in science and invention and upon movements in the social structure.

The most important causes of change in highway utilization and improvement, viewed nationally and in the mass, have in themselves a variety of checks and balances which determine their actual course and influence. For example, the national market for large numbers of motor vehicles has resulted in the investment of so much capital, the growth of industrial plants of such large dimensions, and the establishment of such complicated routine of production, that year-to-year changes in the product are limited by the necessity of conserving the investment in plant, by the requirements of mass production, and by considerations of time. Thus, the change in the motor vehicle becomes definitely pronounced over a fairly long period, rather than from year to year.

---

[2] Chf., U. S. Bureau of Public Roads, Washington, D. C.

The most serious loss in the highway investment over the decade 1928–1938 is the obsolescence resulting from changes in the number and speed of motor vehicles operating on the highways.

The revenues accruing to the public treasuries from the special taxes levied upon the motor vehicle and its users in all the various forms have been increasing in their total over a long period except for the temporary recession during the worst of the depression years.

First intended and levied for highway improvement, the growth of income from these special taxes should permit highway officials to build more adequate and, consequently, more costly roads. However, because there have been large diversions of this income to other purposes, and because these funds have been spread over an ever-increasing mileage, many States are faced with a constantly growing financial dilemma.

Highway research is moving forward steadily on many "fronts," with definite objectives. The responsibility for carrying on intensive studies, in the physical and economic fields, has been accepted as a continuing obligation by highway engineers and scientists in allied fields. Concurrently, the necessity for greater street and highway safety has become a national emergency.

These are only a few of the factors that will determine the trend of modern highway development, but they are the most important.

Scientific Planning and Administration

Faced with the constantly increasing demand for the construction of new highways and the spreading of the income over a rapidly growing mileage, highway officials, State and Federal, realized the impossible situation which was developing and which, in a number of States, was actually current. Out of this situation was born the State-wide highway planning surveys which are now (1938) being conducted co-operatively in forty-four States and in the Territory of Hawaii. These surveys and supplemental studies will present a factual basis upon which to plan the complete administration of all the highways based upon sound principles and factual data. One of their important phases is the determination of the relation of the highways to other types of transportation and communication and to population distribution.

Beginning with water transportation and continued by railroad development, the influence of transportation in the past has been exerted to concentrate large populations in small areas. It is only necessary to examine maps of the United States, or any other country, to visualize clearly the concentrations of population in cities which have resulted inevitably from the characteristics of waterway and railway transportation.

Highway transportation by motor vehicle is the first great decentralizing transportation agency. The first notable effect of this dispersing influence is the formation of the wide bands of suburban development around the cities. Even cities of moderate size have developed, within a decade, a suburban band 5 to 10 miles in width (and depending upon topography) partly or completely enveloping the old city. The automobile, in conjunction with rail suburban service, has attracted city workers to make their homes in rural districts for distances easily as great as 50 miles from the city.

The next logical step is the break-down of over-sized industrial units into smaller units that will be free of many of the undesirable characteristics of over-concentration, yet will be of sufficient size to retain the economies of mass production. Sufficient progress in this direction has already occurred to indicate how inevitable must be this process even if slow. It is reasonably well established that economy of production can be secured in units of moderate size, and the national thought along social lines is becoming a potent force toward decentralization because of the opportunities presented for a more healthful and more desirable mode of life for the workers and their families.

It will be noted that no conjecture or uncertainty is involved in these statements, but simply a recognition of existing facts. The implications are clear that the scientific planning of highways and highway systems of State-wide and nation-wide dimensions will be the most characteristic trend in highway development.

Without such scientific administration there will be no possibility of providing adequate highways to serve both urban and rural needs, or to keep the cost of highway improvement, including maintenance, within the limits of revenues that can be raised by reasonable road-user taxes. This means a reversal of the present trend in many States where the maintenance cost of the rapidly growing mileage of local, poorly built roads is mortgaging far too large a portion of the highway budget. This situation has been produced largely by legal mandate and other public policies adopted and pushed into effect without any consideration for sound highway administration. The nation-wide movement, through the State and Federal highway departments, to place highway administration on a sound economic engineering basis, is not only the most important trend, but is also the cause of other trends which, on this account, may be predicted with some certainty. Out of the planning surveys will come definite specifications for the division of highways into groups classified by the service they are called upon to perform. By research and experience the details are being rapidly defined, that will determine the general type of highway design for each highway service group. In this field the principal items will be the alignment with limiting curves, sight distances, the number of traffic lanes, their widths, the shoulder widths, divided roadways for multiple-lane highways, and many other details.

Design Problems

The trend here is, first, to classify highways, based upon service, and then to design closely in accord with the classification—contrasting with the all too prevalent practice, in the past, of applying single standards to long mileages, and without change, to roads of widely varying traffic service requirements.

In the field of highway design, the most important single development is found in the possibilities of soil stabilization. The intensive research work of more than a decade has borne fruit in the understanding that now exists of the physical and chemical properties of soils, and methods of utilizing the knowledge no longer stop at mere superficial applications to the immediate sub-grade, but go further, to affect the entire graded road-bed in both cut and fill sections. Among the most important additions ever made to the highway organization are the soil technician and his specialized soils laboratory. The application on a broad front, of this new knowledge will come as rapidly as engineers may be given the specialized training, and as a result there will be, for the first time, the possibility of building really scientifically designed roadway sections since these will be placed upon foundations of predictable behavior.

With a large program of grade separation under way at railway and highway intersections, and with the changed public policy in paying construction costs largely from public funds, grade-crossing elimination has become a fixed policy that will continue until all important railway-highway grade crossings have been eliminated, and minor ones protected by adequate devices.

This same policy is being rapidly extended to the separation of important highways at intersections, and one of the important trends of highway design in the immediate future will be to rule out intersections at grade as a possibility in efficient highway design.

In this connection, incidentally, the widespread use of "stop" and "go" lights is not a solution for traffic movement, but has been a development of necessity imposed upon a system of highways designed and built before the present dimensions or speeds of highway traffic were considered possible. Obviously, the trend of highway improvement in the future must be to provide flow arteries in the congested-area traffic that will permit continuous flow of traffic from down-town areas well into the suburban areas. Although the cost will be high, it is only through such arteries that capital, invested now in land and buildings in the hearts of the business districts, can be even reasonably preserved.

The pioneer roadway, even on main traffic routes, was conceived as the single important objective. Now, with the recognition of values inherent in highway transportation beyond the bare utility, the roadway design has come to embrace the entire right of way. The trend of modern design is to provide landscaping of the roadsides, sidewalks, foot paths, bridle paths, and to stop, and protect against, soil erosion. The required additional attention and expense are paying large dividends through greater durability and through the recreational values inherent in attractive waysides.

Super-Highways

There is more or less discussion in which the term "super-highways" is used without any adequate definition of what is intended by this term. Perhaps, it is more frequently used in connection with a very limited number of transcontinental highways designed for high speed and with multiple-lane roadways to carry traffic from coast to coast.

The German system of super-highways embodies this idea. In that country a system of about 4 500 miles of highways (which gives approximately three lines across the nation in each direction) is constructed on entirely new, wide rights of way without access from abutting lands, except at infrequent intervals. This design is for high-speed, motor-vehicle, through traffic. The travel section is composed of two roadways about 30 ft wide, separated by a parking. Both the horizontal and the vertical alignments are exceptionally good. All cross-traffic is directed over or under these highways. No detail that comes within the purview of highway engineering that will make a safer or more efficient highway has been omitted. The most advanced highway design technique has been embodied in this development. The economic utilization is not so clear.

In the United States there is need for a considerable mileage of highways having similar characteristics, but the disposition of this mileage, to be most efficient, must be planned on the basis of the careful studies now going forward. The system of German roads is being built in advance of, and to promote the development of, highway transport. In the United States the situation is just the reverse. Highway builders are proceeding on the principle that the utilization of the highways must produce directly the revenues with which to finance their construction. As long as the United States adheres to this method of financing, the building of super-highways must be limited to areas where the present and prospective traffic will justify it. As a trend of highway development, it is apparent, from the important beginnings already made, that a considerable mileage of motor super-highways will be developed, that their location will be carefully integrated with the population centers, and that the layout will not be on the transcontinental basis.

In France, where a system of national roads has been developed over a long period, the present construction is to take care of the traffic around the metropolitan districts, particularly the vicinity of Paris, by a system of circumferential and radial roads in combination. The detail of outstanding importance in this design is the separation of cross-traffic.

From the developments abroad and in the United States, one can conclude that super-highways will be created, but only in the vicinity of metropolitan areas, for relieving traffic congestion within these areas and for connecting those that are separated by relatively short distances. The first function has already been served to a considerable extent by parkways. It is logical that there will be further developments of the type of the Blue Ridge Parkway designed to connect the Shenandoah and the Great Smoky Mountain National Parks. The development of such parkways recognizes the large use of motor vehicles for recreational purposes.

THE INFLUENCE ON POPULATION CHANGES

Finally, the power of highway improvement to accelerate the shift of population from areas of low productive potentials to those more favorably conditioned will be consciously used in the national policies developed for the long-term attack upon land-use problems. A definite start is already being made in this direction and will become more apparent in the layout of the system of secondary or feeder roads. This thought definitely emphasizes that the country has completed the pioneer stage of road development and every trend of highway development of the future must be an intelligent meeting of the particular service to be rendered.

TRUNK-LINE HIGHWAYS IN METROPOLITAN AREAS

By Leroy C. Smith,[3] M. Am. Soc. C. E.

Synopsis

Elements essential to a master plan for trunk-line highways are discussed in this paper. The application of such a plan to the Metropolitan Area of Detroit, Mich., is offered as an illustration.

Introduction

Metropolitan areas in the United States are still in a condition of flux—the lines that might confine such an area to-day will, in general, be outgrown to-morrow; the uses made of any part of the area to-day may not be the uses of to-morrow; the pleasure route of to-day may become the industrial highway of to-morrow; the traffic and population of to-day will be greater to-morrow; the cross-roads at major highways of to-day may be a secondary center of to-morrow; and, unless the hub of the area of to-day is adequately served by arterial routes, it will not be, to the same extent, the hub of to-morrow.

Certainly, no one influence has been more responsible in giving impetus to the changes that are occurring in metropolitan areas, and to the uncertainties of the ultimate crystallization that may occur, than the automobile; and, certainly, there is no saturation point in evidence in the usage of automobiles or in their numbers. In the first place, the ratio of the number of automobiles to the number of people is still on the increase and, at the same time, the population is increasing. In the second place, it is becoming increasingly apparent that the sphere of use and influence of the truck and bus is enlarging, and it is dangerous to attempt to define their probable limitations.

This condition of flux and uncertainty as to the ultimate demands that may be made on trunk-line highways in metropolitan areas would present a much more complicated problem to the highway engineer in planning for the future, if it were not for the axiomatic fact that the essence of the solution lies in providing adequate right of way, and that such right of way is essential to any plan and to any use which may ultimately be made of any such highway.

Essential Elements of a Plan

The first step must be a plan providing for a system of trunk-line highways, so located and of such widths that the future highway requirements of the entire area can be met. Although, perhaps, it may be necessary to reinforce such a plan with layouts showing the ultimate developments requiring those widths, the engineer should remember that radically different details may be required to meet the results of changing conditions, but that with adequate right of way available the future can be viewed with confidence.

---

[3] Chf. County Highway Engr., Wayne County Road Commrs., Detroit, Mich.

Such a plan will provide for certain distinct locations and frequency of trunk-line highways to serve the various primary needs of the area, and will include:

(1) Arterial highways piercing to the hub of the area from the hinterland outside the area.

(2) Traffic headers or trunk-line loops which may serve several purposes, such as:

- (*a*) Permitting through traffic to by-pass congested areas and to avoid the hub of the metropolitan area.
- (*b*) Distributing traffic of the several arterial highways to the local street system and *vice versa.*
- (*c*) Meeting the demands of periods of peak loadings, such as Sundays and holidays in the case of pleasure traffic, or daily commercial peaks and seasonal conditions affecting industrial traffic.
- (*d*) Cross-town arteries for local traffic. Ultimately, in many cases, this may become the major function of certain such headers or loops.

(3) Boulevards and parkways for the exclusive use of pleasure traffic and to serve the recreational needs of the area.

(4) Secondary highways which are not quite trunk line in character but which are dispersed at frequent intervals as major local streets within the trunk-line network.

(5) Some of these trunk-line highways must meet the present and ultimate needs of mass transportation, whether on rails or rubber.

(6) Express roadways with separated opposite-direction free-traffic lanes may be provided in certain highways; or, the entire highway may become an express-way from which local traffic is excluded, except at long intervals and definite points; and, in still other cases, the entire highway may become a free-way without vehicular access from abutting property.

(7) Such trunk-line highways must almost invariably serve the needs of the area as trunk lines for public utilities, and inadequacy of right of way, in addition to cramping the highway possibilities and increasing the cost of the ultimate highway development, will affect the utilities in the same way. The public pays the cost of both. The minimum provision for such utilities may become a controlling factor in determining the width of the right of way in certain special cases, as, for example, a trunk line that becomes a subway route.

(8) Super-highways having sufficient right of way to permit all highway functions to be combined in one highway at grade, including provisions for mass transportation and local service to abutting property and complete grade separation and interchange at major intersections. In certain conditions such a super-highway may carry several highway functions on an elevated structure in a right of way sufficient to contain such elevated structure adequately, and the elevated structure may become a free-way without depriving abutting property and local traffic from the use of the highway at grade.

(9) Double-decked streets in which the entire right of way is used on two levels. This is a special case applicable generally only in extremely congested

areas where a built-up condition and right-of-way costs preclude other solutions. This subject will not be dealt with in this paper.

(10) Parking facilities. It is a moot point whether such facilities should be provided in highways.

Except in the case of a few of the major metropolitan areas of the United States, and except for the present need of widenings or other provisions to relieve "bottle-necks" and lack of capacity existing on arterial streets of most cities, there is usually no immediate necessity for making or deciding the ultimate structural development of the system of trunk-line highways. The immediate need is for a system of rights of way of adequate width and location and if that need is recognized, the future is reasonably insured. Structural development of such rights of way can be progressive as the need arises.

RIGHT-OF-WAY WIDTH

The Master Plan for the Metropolitan Area of Detroit fixes a minimum width of 120 ft for right of way of trunk-line highways. For secondary highways, as mentioned in Item (5), the plan calls for a minimum width of 86 ft and, for super-highways, a width of 204 ft.

Boulevards serve as something more than traffic arteries and the right of way must be sufficient not only for traffic needs but also to permit some beautification and park characteristics. A right of way 150 ft wide is a practical minimum and will permit two roadways each 36 ft wide, a center parkway strip, 38 ft wide, and 20 ft on each side for pedestrians, plantings, etc.

Parkways are essentially long narrow parks, served by an included roadway which is not directly accessible to local abutting property, and are generally planned to have grades separated at major intersections. The right of way is usually variable to conform to local topographic features; at minimum sections, however, it should not be less than 200 ft. Topographically, parkways often follow streams; they utilize low-lying stream valleys and, in such locations, can often be carried into and through comparatively well developed areas at relatively small cost, thereby replacing unsightly stream-valley dumps with a value that will enhance parkway facility.

MASTER PLAN FOR THE METROPOLITAN AREA OF DETROIT, MICHIGAN

In 1925, acting in conjunction with the Rapid Transit Commission of Detroit, the authorities controlling streets and roads in the metropolitan area adopted a Master Plan for the area. Although the plan dealt primarily with conditions within a 15-mile circle from the City Hall, the essential elements extend over a much larger area.

The plan provided that on each section line a right of way 120 ft wide would be available and that at every third section line the right of way would be 204 ft wide. The right-of-way width for roads on quarter-section lines is 86 ft. In addition, it provided that the right of way for the six major radial arterial highways (Fort Street, Michigan Avenue, Grand River Avenue, Northwestern Highway, Woodward Avenue, and Gratiot Avenue) would be 204 ft wide beyond the Six-Mile Circle (approximately) and 120 ft wide within that circle. Actually, these radial arteries have already been made 204 ft wide, and the system of 120-ft highways has been adhered to for many miles beyond the 15-mile limit of the original plan.

It may be well to explain that these radial arterial highways are of more than local significance and are, in fact, the major routes to the various sections of the State and to the neighboring States.

Five radial highways were established in 1825 under the direction of Governor Lewis Cass as the five great military highways for this section of the country. With a right-of-way width of 100 ft (which in many cases has since been encroached upon), they radiated in all directions and comprise the River Road, from Detroit to Perrysburg (Toledo), Ohio; Michigan Avenue, from Detroit to Fort Dearborn, in Chicago, Ill.; Grand River Road, from Detroit to the mouth of the Grand River, at Lake Michigan, on the west coast of the State; Woodward Avenue, from Detroit to Fort Saginaw, Mich., the major artery running north through the State; and Gratiot Avenue, from Detroit to Fort Gratiot north to Port Huron, Mich. (serving the "thumb" district of Michigan).

These five arteries are now super-highways under the plan, except River Road, the major portion of the traffic from which is locally taken by the Fort Superhighway. The sixth radial arterial highway, Northwestern Superhighway, is of recent origin and, although at present it terminates in the resort lake region of the adjacent county, it is ultimately projected to be extended northwesterly through the State to Ludington, on Lake Michigan.

Fig. 5 shows the Master Plan. It will be noted that more than 80% of the 204-ft rights of way for super-highways has already been secured as well as most of the land for all lesser widths. Furthermore, on the super-highway sections of the aforementioned six radial arteries, double pavement sufficient for present needs has been built, and the same is also true on seven other super-highways (Base Line, Mound, Kelly, Stephenson, Southfield, Schoolcraft, and, partly, on Telegraph).

In addition, 38 miles of the 42 miles of the Outer Drive have been constructed as a boulevard on a 150-ft right of way and many of the 120-ft trunk-line highways have been developed. Several parks have been acquired and developed, a plan for parks and parkways has been adopted, and a parkway more than 8 miles long has been completed on right of way varying from 250 ft to approximately ½ mile in width.

This progress since 1925 (when practically no right of way wider than 100 ft existed for any of these highways and only an inconsiderable part of that width) has been attained on a pay-as-you-go basis, without bond issues, and has been largely due to the following factors: (1) The unanimous adoption of a plan; (2) legislation enforcing the plan on sub-dividers of property; (3) adequate condemnation legislation; and (4) conserving automobile taxes to highway uses.

In respect to radial arterial highways, the Master Plan provided that they would be super-highways and the reduction from 204-ft width to 120-ft width at the Six Mile Circle (approximately) was predicated in layouts showing that, by carrying provisions for mass transportation in a 4-lane or 4-track subway

below the 120-ft street, that street would have approximately the capacity of the 204-ft super-highway.

The congestion of surface traffic on these radial arterial streets within the Six Mile Circle had already reached a stage which demanded immediate widening, and the width adopted was 120 ft, with the aforesaid layout as a background. Since that time these widenings for Woodward, Gratiot, and Michigan Avenues have been almost completed, a start has been made on the others, and steady progress is under way toward ultimate completion of this element of the plan. Thus, the entire original Master Plan is almost a reality to-day (1938) in so far as ultimate widths of right of way with sufficient development for the needs of to-day are concerned.

SUPPLEMENTARY PLAN

With these several great super-highways converging toward down-town Detroit, the Wayne County Road Commission believed that they should be extended into, and connected across, the city proper on similar widths of right of way. Accordingly, a plan to accomplish this end was presented in a report to the County Board of Supervisors and adopted in principle. This plan calls for the widening of unimportant streets through the unprosperous area of old Detroit to provide new 204-ft thoroughfares. By means of 61 miles of such highways, all the outlying super-highways will be connected to a down-town loop approximately 1 mile square. This supplementary plan is shown in Fig. 5.

In presenting this plan the Road Commission was influenced by the following considerations:

(1) It is improbable that the few arterial streets that are being widened to 120 ft will prove adequate if the central section of the city is to be properly served in the long future and if the high values and concentrated uses of the down-town area are to be preserved.

(2) The cost of utilizing these 120-ft streets ultimately to accommodate the future capacity of the 204-ft super-highways feeding into them, will be so great that the excess cost in sub-surface works would finance a better and less expensive plan and additional and more adequate arteries in other locations.

(3) The supplementary plan would open blighted areas to renewed prosperity and would traverse sections of the city now inadequately served. The street widening in stagnant sections, where lots and buildings are of little value, will increase values along these new thoroughfares, the highest type of development will be attracted to these broad thoroughfares, and the central area of Detroit will be enabled to expand to meet future demands.

(4) The width of 204 ft can often be secured at a cost not appreciably greater than a much lesser width.

Having in mind the general street layout it is found that, in condemnation processes to widen a street to 120 ft, the taking line, whether the widening is on one or both sides of the street, passes through all buildings. The result is that the award, besides covering the land taken and damages to the remainder of the land parcel, also includes a value for the part of the building taken and damages to the remainder of such building as well as an allowance for business loss during alteration. These latter items approximate the reconstruction cost of the building.

On the other hand, if the widening is all on one side of the street and if the entire parcel is taken, only the present value of the property is involved, and that value may be less than the composite damages awarded. If the widening is so laid out, it will generally produce a street width of at least 186 ft, including the present street (say, 66 ft), the lot depth (say, 100 ft), and the alley width (say, 20 ft). In many cases it will produce even more, but in any event the condemnation of an additional strip, 18 ft or less in width, off the rear of the next and much cheaper series of lots, will produce the desired 204 ft.

Rapid Transit by Rail and Express Highways

Rapid transit, whether on rail or rubber, demands freedom from traffic lights and from local traffic interference. Although express highways and free-ways built at grade with grades separated at major intersections may be possible for outlying districts, the permanence and adequacy of such a solution, as the future develops, is open to question. Exclusion of local traffic and of abutting property from use of the facility, if at grade, makes of it a Chinese Wall as the territory develops. To be effective rapid transit by rail and express highways must be above or below grade and local needs must be met at grade.

Layouts and perspectives prove the possibilities of the 204-ft right of way to permit facilities for mass and rapid transit on rail and on express highways, together with adequate surface facilities for local traffic. Furthermore, at intersections, such right of way will permit complete grade separation and, at the same time, complete local interchange. In the case where these rapid transit facilities are on an elevated structure, it will be noted that the area below the structure provides valuable parking space in addition to location for surface street cars. It will be noted, furthermore, that if in the future mass transportation on rubber rather than by rail becomes the rule, a much simpler structure can be adopted.

The usual objections to elevated structures are minimized or overcome if the street width is such that adequate roadways at grade flank the structure, and under such conditions the structure can become one of beauty rather than ugliness and, through proper design, noisiness can be reduced to a point where it becomes non-objectionable. In general, where such an elevated structure accommodates both rail and rubber express-ways the part of the width utilized at one point for express loading platforms will be used at another for local loading platforms of the rail facility, and at still other points will be utilized by the ramps to and from the motor express-way.

Another plan for express-ways or free-ways which is worthy of consideration to meet the needs of arterial highways in congested districts where property values are high, would entail the use of the alleys at the rear for single-direction elevated express-ways. This is particularly applicable if there is a legal method provided for condemning air rights.

Assuming a 20-ft alley, the construction of a 30-ft express-way would entail the use of approximately 8 ft of air rights on each side of the alley; a 40-ft express-way would require air rights over approximately 13 ft on each side.

In addition, unless it proved feasible to cantilever the part of the structure occupying the strip of air rights, it would be necessary to condemn occasional small areas (probably at the lot lines) to accommodate columns and footings.

At long intervals such express-ways would be served by ramps to and from the surface and, at those locations, additional condemnation will be unavoidable. The space under such a structure, on private property, could serve all present uses; or it could be enclosed to enhance those uses, or to provide new uses. The height of the structure would be governed by present uses and by minimum clearances at cross-streets or at crossings of similar elevated structures. The cost of increasing the height to meet local considerations is relatively small.

Given legal condemnation of air rights still another plan is applicable in certain instances. Predicated on the fact that railroad rights of way pierce most cities in a strategic manner, the use of air rights for elevated highways over such available routes would add express-ways or elevated highways for industrial uses where they would be most effective. However, consideration of such a plan must include weighing carefully certain opposing factors:

(*a*) It is important that the elasticity of the railroad facility to expand or to be altered to meet future needs be conserved (this is as important as any highway function).

(*b*) Such a plan may entail partial or complete electrification of the complicated terminals of the railroads at a cost that would preclude its further consideration.

Another general observation on the problem of rapid transit by rail or express-highways is that sub-surface structures are almost invariably much more costly than elevated structures. In many cases the excess cost of a facility of ample proportions below grade is so great that new and ample right of way in parallel locations can be secured and served by an elevated structure at less cost.

Furthermore, the use of sub-surface structures is much more inelastic; if designed for rails, it cannot (except with further additions at great expense) be used for highway traffic. On the other hand, the change from a rail facility to a highway facility, or *vice versa*, is easily accomplished in an elevated structure.

PARKING

It is difficult to foresee what the future may demand in the way of parking facilities as an adjunct of the highway.

In considering long-range highway and street plans the engineer should not pass the parking problem with a gesture and the assertion that parking is not a highway function. Perhaps the following comments may point to a future trend:

(1) The automobile owner now pays the cost of parking and at a high rate. The money comes from the same pockets as the highway money, and the expense is an unavoidable part of the cost of the highway transportation system.

(2) The present investments in covered parking facilities run into millions and, in addition, the public pays an enormous price for parking in open lots.

(3) Perhaps the cost of this element of highway transportation would be less if it were planned to be included in the highway system and, with adequate rights of way, it is conceivable that sub-surface regions, or elevated layouts, could be utilized for the purpose. In cases where ultimate development of the trunk-line highway in congested districts is through the use of elevated structures flanked by streets at grade, the space at grade below the structures may become a valuable parking area and its value in that regard may be a partial justification for the adoption of any elevated plan.

(4) If often occurs that all of a parcel of property or of contiguous parcels may be secured quite apparently at no greater cost than the pay needed for the highway width. Perhaps, if parking were recognized legally as a highway function, there would be justification for, and necessity could be proved for, taking such excess property for such use.

(5) The value of such facilities is recognized by business, particularly those businesses which are responsible for the growing trend toward decentralization through the establishment of smaller concentrated business centers in outlying districts. In many such cases the store or group of stores involved are providing free parking facilities (sometimes on a large scale) for patrons. This is perhaps a major factor in the growing success of such outlying business centers.

To a large extent such decentralization is at the expense of existing businesses and property values in the heart of the metropolitan area. To the extent that a plan aims to conserve such central values it should, perhaps, take cognizance of the parking problem as being a considerable factor.

Legislation to Make Plans Effective

A plan of a system of trunk-line routes with adequate right of way, adopted by all highway authorities of the metropolitan area, is essential to real and steady progress; but it is impotent and unproductive in the absence of legislation to enforce it, to preserve it from encroachments or abandonments, and to provide adequate methods for obtaining right of way by condemnation and otherwise.

Perhaps a review of the legislation of Michigan which has been found effective in creating, rapidly, a network of adequate rights of way in accordance with a definite plan for the Metropolitan Area of Detroit, may not be amiss even if the underlying constitutional provisions, highway laws, etc., may not be quite duplicated in other States.

The fundamental highway laws of Michigan set up jurisdictions, etc., as follows:

(1) Except as affected by home-rule constitutional provisions in the case of incorporated cities and villages, the State Highway Commissioner has jurisdiction over State trunk-line highways and is required to meet one-half the cost of maintenance, widening, and betterment thereof in metropolitan communities of the population of Detroit.[4]

(2) All other highways and sub-division streets and alleys, except in incorporated communities, are under the jurisdiction of each County Road Com-

---

[4] PA 131 of 1931 amending Section 1 of PA 19 of 1919.

mission. With the consent of the incorporated community such commission may take jurisdiction over any street or part thereof within the community. Such commission is also empowered to take over, in whole or in part, the obligation of any such community arising out of a contract with the State Highway Commissioner in conection with the widening or improvement of a street which is a State trunk-line; and, in connection therewith, or as may be entailed on streets taken over by the commission, it may condemn property within the community.

Super-Highway Law.—Shortly after the Master Plan for the Metropolitan Area of Detroit was adopted by all municipalities and highway authorities, an effective legal instrument was made available in the super-highway law[5] which included the following:

(*a*) A contract may be entered into by boards of supervisors, and a super-highway commission can be formed by any two or more adjacent counties; and such commission includes the three members of the respective County Road Commissions and the State Highway Commissioner.

(*b*) Super-highways are defined as including highways of widths varying from 106 to 204 ft, or more.

(*c*) It is the duty of the super-highway commission to prepare and record a plan of the proposed highways and their widths, and where there are existing highways the plan must show on which side of the road private property is to be used for the widening. After recording of the plan no plat of land shall be accepted which does not conform thereto.

(*d*) The law sets up a limitation of 0.5 mill property tax in each county for the use of the commission. Except to cover the initial office expenses involved, this section of the law was never utilized and, in practice, each road commission has acquired right of way at its own expense from other funds (automobile tax revenues).

(*e*) The commission can accept donations of land and property and dedications of land, and may purchase, option, or condemn land.

The major effect of this legislation was to enforce the plan on sub-dividers of property and through that provision alone dedication of many miles of frontage in accordance with the plan was secured without cost, thereby saving millions of dollars.

Approval of Plats.—If a plat of property includes county roads or State trunk-line or Federal Aid roads, it must be submitted to the County Road Commission or the State Highway Commissioner for approval before being eligible for recording.[6]

Abandonments.—Although a Court may vacate a plat, it cannot abandon any part of a county road or State trunk-line highway. Such highway can be abandoned in whole or in part only by the County Road Commission or the State Highway Commissioner as the case may be. Abandonment by the County Road Commission must be recorded. Thus, the right of way, once secured, cannot be abandoned except by these authorities.[7]

---

[5] PA 381 of 1925.

[6] Sections 31 to 37, PA 172 of 1929.

[7] Section 66 of PA 172 of 1929; Section 18 of Ch. 4, PA 283 of 1909 being Section 3993 of Compiled Laws (1929) as amended by PA 135 of 1935.

Encroachments.—Title to any part of the right of way of a highway cannot be secured by adverse possession.[8]

Condemnations.—County road commissions and the State Highway Commissioner have several methods of condemnation available: (1) By jury under two Acts;[9] (2) by a commission of three appointed by the Circuit or Probate Court;[10] and, (3) immediate possession after hearing of necessity and after tender of damages estimated by the County Road Commission. If tender is not accepted, condemnation must be done by processes provided to determine damages.[11]

Set-Backs Without Excess Condemnation.—If lots at the rear of the lots desired can be secured by agreement and if owners of front lots will accept a set-back by agreement, this process can be adopted. In outlying districts this provision has enabled the purchase of much frontage at the price of interior lots.[12]

Conveying Title.—By statute, County Road Commissions are incorporated bodies and are empowered to convey title to lands held by them and which are not a part of, or required to be used for, a road or park.[13]

May Condemn All of a Lot.—County Road Commissions can take all of a lot (if such part is required for the public improvement) as will destroy the value of the remainder as a single parcel or lot.[12]

Needed Legislation.—To meet the future, as the need presents itself, legislation may become necessary for condemnation of air rights, and for the exclusion of abutting property from access to free-ways. Free-way legislation has been enacted in the States of New York and Rhode Island.[14] Quoting from *Information Bulletin No. 36*, issued by the Regional Plan Association of New York:

> "This act [the Rhode Island act] is to be recommended for its directness and simplicity of treatment.
>
> "The adoption of freeway legislation by these two States may be hailed as the beginning of the most significant movement in several years in the progress of highway development. A look into the future would envision the idea extended to the other states of the Nation, expanded to include county and local highway departments and perhaps influencing the program of Federal highway aid."

DISCUSSION

F. Lavis,[15] M. Am. Soc. C. E. (by letter).—The writer has been much interested in the paper by Mr. MacDonald, whose point of view is based on actual practice; but so much has been written during the past year or two about the "Highway of the Future" that the layman will expect this to develop at once into a clear, uninterrupted, wide pavement with cars "sailing along" at 100 miles per hr, or faster, with no stops for traffic lights or interference by traffic police, no grade crossings, no cars stopped on the pavement or traveled way, all traffic lanes separated, and perhaps (the Utopia) no noticeable expansion joints to mar the smoothness of the pavement.

With this ideal situation, pipes, sewers, and conduits will be laid outside the traveled way, so that pavements need never be disturbed and these latter will be so durable that they need never be relaid. There will be wide shoulders and rights of way, and the roadside will be beautifully landscaped.

In 1937, a speaker was reported by the Associated Press to have told the National Planning Conference in Detroit, Mich., that, "The American street and highway system must be scrapped and rebuilt unless the automobile is to become a malignant growth." "We cannot," he said "look with tolerance upon shackles which fetter this newest servant of mankind"; and then he also blamed the highway structure for the great toll of accidents on it.

Apparently, it is to be taken for granted that in this Utopia, the motor vehicles themselves will be of supreme design and construction, built of materials that cannot fail, that will have no mechanical defects, that will, perhaps, take their fuel out of the air so as to avoid stopping, and will be driven by supermen from Mars. The latter is the most essential because the frail humanity of this day and age has apparently not cultivated the skill and stamina to take advantage of these transcendental highways and vehicles, and as one reviews the slow progress in the development of the human machine it scarcely seems likely that succeeding generations will attain the ability and skill to operate these super-motor vehicles about which so much is being written.

The writer is entirely serious in attempting to create this vision because it must be given consideration. It is being preached in many quarters, not by laymen alone but by engineers—engineers who claim that most of their fellow craftsmen have no thought for the morrow, no vision of the future. These statements must be given consideration, but consideration based on some sanity.

The writer is not unmindful of the developments in both cars and highways of the past thirty years, since the time that he bought his first car in 1908 and thought a 100-mile drive in a day was a feat, a perilous adventure, and a difficult, grueling task. Without effort, he can compare that car with the car of to-day, which will go the 100 miles in a few hours with almost no apparent effort either on the part of the car or of the driver; and he has no doubt that similar or even greater progress will continue.

---

[15] Cons. Engr., New York, N. Y.

After looking at these visions, however, engineers should look at the realities of this long-distance planning and attempted provision for the future and visualize the real status of their attitude toward the highway of the future (which is being built to-day), and think about these problems with sense and with their "feet on the ground."

It may be fairly claimed that highway engineers and highway authorities, without having indulged in any extravagant visions of the future, have contributed their share to this advance, and their progress to date has fully kept pace with that of the automotive engineer. There is no reason why they may not be expected to continue going along together.

The writer is not opposed to planning. For many years, while engaged in the planning and design of railroads, his work has been nothing but a long attempt to forecast the future properly and reasonably, and to build for the future, but always with the brake on his enthusiasm of having to "make a dollar earn the most interest." It seems to be a most desirable training for engineers to have been connected with commercial enterprises. Engineers building highways with public funds would do well to think, for some years to come, of the need of making public dollars earn the most interest rather than of providing special facilities for the few or of building highways for excessively high speeds.

It is trite to state that one should do the greatest good to the greatest number; but trite or not, it is one of the great duties of the engineer who spends public monies, and perhaps particularly that of the engineer who directs the spending of them for highways. This does not gainsay the fact that returns from the expenditures of public monies may reach the dollar stage, through health and happiness from recreation; but engineers should be reasonably certain that there is a real return some way or other, and that this return should be a return to the people at large and not to a special few.

Writers on highway subjects during the past year or two have very generally stressed two things: (1) The great number of highway accidents; and (2) the need of "building safety into highways." Strangely enough, many who have deplored the accidents and urged engineers to "do something about it," talk about designing highways for speeds of 100 miles per hr, or even more. They point to the fact that the motor vehicle is being improved every year and that when a highway is built it must remain unchanged for a long time. Consequently, one must build to-day the highway that will meet the requirements of 10, 15, 20, or 25 yr hence, and that, at first thought (and maybe on second thought) seems a very valid argument, particularly if the human element behind the wheel of the car is ignored.

The highest types of modern pavements may be expected to have a life of 20 or 25 yr, even under heavy traffic. There is no possible reason, therefore, for denying the responsibility of the engineer in laying them out so that the most use may be obtained from them during their life.

Accidents and accident prevention are primary topics of consideration to-day, and accidents on highways are a growing menace to the entire body politic. Furthermore, the prevalence of accidents is now tending to be greater in the open country, in the rural districts, than in cities and congested areas. British experience in this respect, coincides with that of the United States, and a reasonable inference from this information is that excessive speeds are a predominant cause.

It has been quite generally stated that 85% of all accidents are caused by the failure of the human element, the driver of the car. On the other hand, it is claimed that accident reports do not show the extent or the occasions in which the highway structure itself is the cause. Admitting that this may be true, to some extent, and that, in some cases, faults of the highway structure may contribute to, or aggravate, accidents and possibly increase their severity, it still remains a fact that highway accidents are very largely the result of incompetent and careless driving and excessive speed. Here, again, British statistics and British observers are in accord with those in the United States. A New York State report[16] published in 1937 states: "So long as the motor vehicle is employed as a means of transportation the driver will remain the chief factor in the accident problem."

When writers refer so glibly, therefore, to designing highways for speeds of 100 miles per hr, they not only ignore this very definite fact of human fallibility but they probably are definitely increasing the accident risk. The writer does not believe that design for high speed provides a margin of safety for drivers at lower speeds. Few drivers are capable of driving faster than 40 to 50 miles per hr, with safety to themselves and to the other users of the highways.

This question of speed as it affects the design of highways and their cost is a most important one. Designs based on speeds greater than 50 to 60 miles per hr are not warranted to-day, or by any reasonable consideration of the future.

Most engineers visualize the highway of the future as something in the nature of the trunk-line military "autobahen" created in Germany, the so-called "freeways," or the parkways near New York City, N. Y., in Westchester County, and on Long Island. These are typical of high-capacity highways in open country. There are also the great arterial highways through congested areas such as New Jersey Route 25, from the Holland Tunnel to Elizabeth, of which the Pulaski Skyway is a part, the great West Side Highway in New York City, and others of a similar type.

In general, such highways have good alignment, gradients that do not require trucks to reduce speed rates, say, of less than 5%, and four to six traffic lanes with traffic in opposing directions definitely separated by a raised curbed strip, perhaps 3 to 5 ft wide.

All these very expensive roads, however, have been built to meet heavy traffic demands, and they carry large numbers of vehicles. It is well known, of course, that maximum traffic capacity is attained at comparatively low speeds, probably less than 30 to 35 miles per hr. There seems to be little reason, therefore, for assuming speeds much greater than this, certainly not greater than 50 to 60 miles per hr, in designing such roads.

---

[16] Annual Rept., New York State Bureau of Taxation and Finance, New York *Herald-Tribune*, July 18, 1937.

Probably the most important task that confronts highway authorities and highway engineers to-day is the provision of sufficient highway capacity to meet traffic demands. This means that new highways, built to-day, should have capacity for meeting the traffic demands of some years to come. Ability to estimate such demands with reasonable accuracy is a necessary qualification for all responsible highway engineers.

Such engineers also should have some reasonable appreciation of the economic relation of expenditures to highway capacity and highway use. Expenditures in this case mean total annual cost—that is, interest on investment, plus annual cost of upkeep. These factors should have a definite relation to traffic volume and operating costs. Of course, highway engineering cannot be entirely evaluated in dollars and cents but the nearer highway engineers can come to such evaluation, the nearer they will approach reasonable economic justification for the large expenditures they make.

The writer is inclined to believe that where there are legitimate criticisms of highway design and highway structures this is due to incompetent engineering rather than to any lack of engineering knowledge by those who keep abreast of the developments of the times. This, however, is not a failing confined to highway engineering alone.

Because of the general nature of highway work as part of a public works program, by which the appointment of engineers and the methods of their functioning may, in some cases, is dictated by political needs and exigencies, there is probably some incompetence in road design and construction and this is especially true in the smaller governmental units and rural districts. Such defects as result from this source cannot be enumerated or specified herein but the writer suspects that these are the defects that cause writers and commentators to refer to certain roads as obsolete before they are completed and to place the blame for accidents on such defects. The remedy is better engineering by properly qualified engineers.

Most important highway officials and engineers are fully alive to the necessity of meeting future needs, and know how to do it; but they evaluate these needs with some sanity and common sense. The writer, however, would like to mention, very briefly, some of the features of modern road construction that should receive general attention.

Most of the States to-day have reasonably well conceived plans of main and secondary highways and are fully alive to the need of adequate surveys both of terrain and traffic. The importance of securing ample rights of way is fairly generally recognized, but there should be a reasonable balance between providing for the future and the permanent alienation of taxable values. It is probably difficult to evolve any formulas that will guide the engineer in adjusting alignment and gradients to the topography. The old-time railroad locating engineer had his Wellington and values for curvature, distance, rise and fall, and rates of gradient. The highway locating engineer of to-day has little to guide him, but experience and judgment. It is here that communities and governments would be wise and well advised in procuring the widest experience and best judgment. Those responsible for highway location should probably err (if they err at all) in laying out the best alignment and gradients they can, to fit the topography and terrain reasonably well. It is suggested that sight-distance diagrams should be developed, at least in all cases of doubt.

The present practice of separating the traffic on four-lane roads by a center strip may well be extended. There is some tendency to build traffic lanes wider than 10 ft. This is a question that should receive careful consideration as to its economic justification. Probably one of the most serious defects of some modern roads is their obstruction by stopped vehicles. Roadside filling stations and eating places probably serve a public need and help taxable property, but provision should be made for stopping vehicles off the main traveled way instead of on it. It is undoubtedly desirable that consideration be given to the provision of sidewalks, at least on some highways.

The provision of reasonably wide hard shoulders and proper forms of side ditches is now generally recognized both as a necessary safety measure and as an aid to increased capacity. It would seem advisable to have all roadside structures set back a reasonable distance from the pavement or traveled way.

It should not be necessary to refer to narrow bridges, except for the fact that so many exist as interruptions to the free flow of traffic on otherwise good roads. It should be a recognized necessary attribute of road improvement that the general newly established character of such roads should be maintained throughout the length of the improvement.

It seems generally desirable that new roads should be designed so that they maintain certain general characteristics of alignment, gradients, width of pavement, etc., for considerable distances; but there seems to be no valid reason, why if proper signs and signals are displayed, changes in these characteristics may not be made if adequate considerations exist to warrant them and drivers are properly notified. A certain standardization of warning signs and the method of their display is most desirable.

All these features are well within the purview of the competent, informed highway engineer of to-day. In view of the needs of the vast network of roads all over the United States, it is doubtful whether highway planners can afford to be too visionary. Grade crossings with other highways and with railways can only be eliminated in special cases. The construction of expensive "freeways" to facilitate certain traffic must be weighed against the needs of the entire highway net and particularly their effect on taxable values of adjacent lands.

Perhaps the time has come when the construction of toll highways for trucks may be considered, but this involves consideration of the economic effect of maintaining the railway system, which seems to be gradually drifting toward Government control and possibly support by the taxpayers. Both railways and highways are tending to become part of one general network of land transportation.

Viewing the entire problem as a whole, it seems that engineers cannot go much further to-day than to adopt the best current practice and to continue improving it as the need arises. What is really needed is to make certain that highway problems are placed and kept in the hands of engineers competent to solve them.

No one expects to stand still, because standing still is really going backward; but, on the other hand, highway engineers are not to be stampeded into attempting to build highways for super-cars, driven by super-men who do not exist.

Engineers (that is, competent engineers) have always been as forward looking and alert as other people—perhaps more so. They should continue to justify that tradition, but should continue trying to make their dollars earn the most interest.

EDGAR DOW GILMAN,[17] M. AM. SOC. C. E. (by letter).—The Symposium entitled "Increasing the Traffic Capacity and Safety of Thoroughfares"[18] raised many of the same questions that the present Symposium now raises.

First, one wonders if, in giving consideration to traffic problems, the word, "traffic," does not mean the movement of all people and not just the movement of motor vehicles. Sidney J. Williams, M. Am. Soc. C. E., in his comment[19] on the Symposium, stated that "much attention has been given to the time lost by automobilists on account of pedestrians, but little attention has been paid to the time lost by pedestrians on account of automobilists." This is a "ray of light" that should be brightened. Traffic regulation should be for masses of people and not for individuals.

Second, although the writer's natural instinct would be to emphasize the importance of the Engineering Profession in traffic problems, studies of hundreds of accidents prove quite conclusively that only a small proportion of accidents are traceable to conditions in which pure engineering is a factor. In fact, there are data to indicate that as engineering improves conditions at certain points, the accidents increase rather than decrease. Some of the points in the city that are obviously the most dangerous have the fewest accidents. The obviousness of the danger seems to be one of the best deterrents to accidents that has been found. As roads are straightened, automobile drivers take more chances and are not as attentive. As a matter of fact, the situation can be summed up in this statement: "If people drove as they should drive, they could drive perfectly safely even in unsafe places."

Studies of events leading to an accident show that the vast majority of accidents are caused by influences that no act of engineering, short of complete separation and isolation of traffic lanes, could avoid. They are caused primarily by foolishness and carelessness, selfishness, lack of courtesy, and lack of consideration on the part of drivers of cars. No mechanical devices or physical rearrangement of streets can be substituted for the manner (or lack of manners) in which people handle automobiles.

The full question of engineering, although important, has been emphasized to the point where automobile drivers use the theory as an alibi for their own actions. This does not mean that the engineering should not be made as beneficial as possible, but engineers are leading themselves into "the hole" of building up a point of view on the part of the public that accidents are the result of something they have done wrong or something they have failed to do, and that drivers themselves cannot be held responsible unless and until the engineering is something highly idealistic and hypothetical and beyond all practical means of attainment. The engineering should go ahead, but the emphasis should be placed on the drivers and not on the engineering.

---

[17] Director, Dept. of Public Utilities, Cincinnati, Ohio.

[18] Transactions, Am. Soc. C. E., Vol. 104 (1939), p. 440.

[19] *Loc. cit.*, p. 504.

Mr. Kettering states (see heading,' 'Lighting—Road or Vehicle?"), "authorities agree on one fact: Night-driving conditions are far behind day-time conditions, and for one reason—lack of adequate lighting and glaring headlights." Many data have been published showing that accidents at night are more numerous than accidents in the day time and in many of the papers including such data the definite conclusion is drawn that this is due to the absence of light, without any consideration of the many other factors in night driving. Of late, a few writers have attempted to proportion these factors properly. Certainly there are enough other factors to justify some question as to whether lack of adequate light on streets and highways is the one reason for a greater number of accidents at night than in the day time.

Nearly all day-time driving is done by people who are soberly intent on the particular accomplishment of a business in hand. It is after the day's work is done that social functions and parties are held. Practically all the driving under the influence of liquor is done at night. Accident records show that this is a big factor. The element of fatigue enters into night driving to a considerably greater extent that it does in day-time driving. Many police records of accidents at night have the notation "Driver fell asleep." All the young men working, and in most cases those not working, use the evening to drive with their "best girls," and their attention is not always on their driving under these conditions.

A mere tabulation of the time of day that accidents occur does not present a justification for the conclusion that night-driving hazards can be reduced at least to day-time driving hazards by lighting the highways. Furthermore, some serious thought should be given to the question as to what would be the effect of illuminating certain highways and not others. It is admitted that it would be impracticable to light all. What will be the effect of lighting some to an extent that will make it safe to go at certain speeds, upon the speed of drivers on other highways where it would not be safe to go at anywhere near those speeds?

If the mental attitude of the mass of drivers could be "built up" to a point where good judgment could be counted upon, this would not be a problem; but in view of records of the immediate past is one justified in assuming that the drivers of cars in mass will exercise good judgment in the manner in which they drive? It is a strange commentary on the entire situation to say that if the streets were studded with cast-iron posts set in the road, requiring automobiles to be driven a tortuous and difficult path, there would probably be no accidents and no traffic deaths. Of course, there would be no speed and no mass movement in short times, and this is not desirable.

It is good engineering to pull out these cast-iron posts from the middle of highways so that automobiles can travel in straight lines, and engineers, very properly, study and eliminate these physical obstructions to movement; but it is a fair question to ask whether they are not improperly designating such things by saying that they are eliminating "hazards" when actually, due to the psychology of the situation, they may many times be adding an intangible type of hazard when they are removing a physical obstacle.

Sometimes, it seems that the public has placed the engineer in a very unfavorable position, that in which engineers are taking the responsibility even where it is not an engineering problem. Coincident with the study of engineering in traffic, engineers should constantly emphasize the fact that the effect of engineering can be but minor on accident records and that deaths and injuries and accidents are largely a result of the action of the people themselves. Although engineers will work to try to get greater utilization of motor vehicles, there is a responsibility on the part of the people who use motor vehicles over which the engineer can have no control.

This feeling that the engineer is responsible for the accidents has progressed to such an extent that there is a one-page article in a popular magazine of recent date rather strongly setting forth the claim that it is the duty of the engineer to separate roadways and crossings and make it impossible for children and pedestrians to get in the path of automobiles. It is a strange mind that can take such a position that this is the sole duty of the engineer. The engineering involved would present no great difficulties. The big problem in the accomplishment of such plans is that of financing, and this means taxes. Engineers can submit billions of dollars worth of plans for eliminating intersectional highway crossings in high-sounding terms of medial and other frictions. The plans will involve a multitude of details, but none that presents insurmountable engineering obstacles. The obstacle to such plans is in the financing and the payment by the public for such idealistic construction. The public has not been able to provide the necessary money with which to eliminate the relatively few railroad grade crossings, and yet in the article referred to the statement is made that it is "up to the engineer" to provide road separations and other tremendously expensive structures.

Engineers should not complacently permit themselves to be thrust into a false position in the traffic situation. They can do much to facilitate traffic movement if people will use their plans as they are supposed to be used. They can do something to add to traffic safety. They cannot do anything that will be a substitute for good judgment, common sense, and decency on the part of the man who has his hands on the wheel and his foot on the accelerator. The attitude of the public itself is the major problem in the safety angle of traffic. The public says it wants safety, but it resents enforcement and there has actually grown up a predominating belief that the problem of traffic safety is a contest in which the police and other enforcement agencies are on one side and the public itself is on the opposite side, fighting against each other. The problem of traffic safety is a problem of mass psychology—the establishment in the minds of the masses of people of the true factors that cause accidents. Engineers are too readily letting this fact sink into oblivion.

George Hartley,[20] Esq. (by letter).—In the group of papers comprising this Symposium a valuable contribution to the art of planning future highways is ably presented. In his interesting résumé, Mr. Kettering has illustrated, splendidly, the possible future of highway travel. The entire Symposium would have been rendered more complete by the inclusion of a few additional details.

The major part of Mr. Kettering's paper evidently represents careful editing of replies to the questionnaire (Items (1) to (18) under "Introduction") by the various contributors listed under "Acknowledgments." It would have been of interest had it been possible to include typical replies or edited replies to show the range of opinion expressed by the various contributors. Views not directly in accord with those of the authors might have been discarded or considered insignificant.

Each of the authors attacks the problem from a theoretical engineering standpoint with only a slight reference to the importance of motor vehicle laws and their relation to engineering design. What good will a highway or motor vehicle, designed for, say, 80 miles per hr, be if some provision is not made to bring the law into such form as to allow speeds approaching this value. Engineers are constantly thinking in terms of increasing speed but, to-day, even on well traveled secondary highways, posted speed limits of 15 and 20 miles per hr are not uncommon and the main express highways, rigorously patrolled, keep travel at a speed representing only a fraction of that for which the highway was designed. Safety proponents are always demanding slower speeds and these bodies are constantly increasing in number and importance. Any serious attempt to revise present highway laws so as to allow increased speeds will surely meet organized opposition.

Some mention should also have been made in regard to some form of standardized financing. Funds for any one structure may come from a number of sources with the subsequent duplication of services. Surely, in a properly planned highway, the financing should be arranged in such form as to permit steady growth and permanence.

Messrs. Smith and Kettering discuss the parking problem in terms of a future Utopia without referring to the parking-meter system. Intended originally as an added tax-gathering system these meters are being installed at a rapid rate in crowded business districts. They create convenient short-time parking in shopping districts where once it was practically impossible to park.

Mr. MacDonald condemns the design practice of the past without due consideration of the fact that these highways were built along single standards, because a certain minimum of width and construction were required regardless of service requirements. That many of these structures are still in service after a score or more years is truly a tribute to their designers. The older bridges in the United States (some of them more than fifty years old) also carry modern traffic. Fifty years ago when the horse and buggy represented the acme of transportation on the highways, who might have forecast or planned future traffic requirements? With their planned programs and improved materials, can engineers to-day design structures that will serve throughout the life of a planned program? May not the entire viewpoint be completely revised in only a few years by new inventions or even the technique of planning itself? If so, the present generation of engineers must, in turn, await the criticism of its successors. The development of express highways to by-pass crowded centers of population may be one of the major factors in causing a revision of planning methods in Germany where the express highway, established on a larger scale than in the United States, is already attracting commercial establishments with the attendant growth of adjacent residential districts.

---

[20] With Robinson & Steinman, New York, N. Y.

ROBERT KINGERY,[21] ESQ. (by letter).—As Mr. Smith states (see heading, "Introduction") no identical pattern or design of a road facility can be transplanted directly from one metropolitan area to another. However, the good designs and successful operation of a given type of highway facility may be adapted to conditions in most metropolitan centers. Without question the original boulevard system in Chicago, Ill., laid out and acquired in 1869 and 1870, has been imitated in many parts of the world. Perhaps the original was an imitation of some other system. Members of the Regional Planning Association of Chicago have profited not only from the Wayne County Highway, and the Detroit Rapid Transit policies, but have studied and have incorporated, in major thoroughfares and super-highway designs, some of the parkway features from Westchester County, New York, and from the Mount Vernon Parkway, near Washington, D. C.

In the ten years since, in 1928, the Chicago Regional Planning Association originally laid out a program of major highways, super-highways, boulevards, or parkways, almost exactly one-fifth of that program has been completed. It is now (1938) advancing at a much more rapid rate. Of the 603-mile system in the 15-county area, 127 miles of right of way from 160 ft to 240 ft in width have been acquired, and 114 miles of pavement have been built, all outside the City of Chicago itself.

Within the city about 14 miles of major trunk traffic artery of the parkway type have been completed along the lake shore from a point 6.5 miles north of the center of the city to a point 7.5 miles south. Entrance to the city from other directions is more difficult, there being no existing broad rights of way. Many studies have been made by the Chicago Plan Commission and by other official and unofficial bodies and now it seems more hopeful than ever before that a decision upon a comprehensive plan will soon be agreed upon, and construction begun by the co-operation of several highway building agencies.

However, one note of caution might be injected into the subject of Mr. Smith's paper. At many meetings of city planners and in many papers about metropolitan highway planning and about zoning one will hear or read of the conception of the dreamer who pictures cities with buildings and towers a thousand feet high, with miles of two-decked, three-decked, and multi-decked highways in centers of population concentration. To some planners this type of thinking is in the wrong direction. There is adequate evidence of the result of excess concentration of population and of commerce in small centers. One example among many is the fact that closely surrounding such an intensive concentration of high buildings is almost always a broad belt in which disintegration is far advanced. The City of Chicago has such a belt, which is 10 miles long and more than 3 miles wide. It covers 36 sq miles, or one-sixth the area of the city; and more than 260 000 people have moved from it during the past twenty years. Many of the tax delinquencies are in this area; and it includes a substantial number of both juvenile and adult delinquencies which form the principal police problem; as well as a substantial majority of fire-protection problems. Tax receipts from this area do not nearly support the governmental services to it. In slightly modified form, the same can be said of every large metropolitan area.

---

[21] Secy., Chicago Regional Planning Assoc., Chicago, Ill.

Although high buildings with multi-decked highways—with masts for the anchorage of dirigibles, with landing fields for the clouds of aeroplanes that are seen in photographs of the "City-of-the-Future"—are all stirring to the imagination, by no means do they involve solvency of the municipal pocket-book.

Construction of highway facilities, of course, will not solve all these problems, but it can come nearer to it. Penetrating the centers of these large cities and surrounding the business centers of them in the so-called blighted areas, the development of exceptionally broad rights of way or parkways with adequate space for pavements—on the ground level, elevated, or depressed—with adequate space for grass and trees will, in the judgment of many, do more to reconstruct the city at its core than almost any other single influence. With the construction of such radial or belt line boulevards (or both), and with the addition of adequate parks and playgrounds in such a zone, and with courageous and intelligent zoning or re-zoning of the neighborhood, property values will be restored for residential occupancy of much of that area.

For some decades too much attention has been given to the construction of buildings in the development of cities in the United States, and too little to their setting and their surroundings. The introduction of more open space in the form of boulevards and parkways is one of the greatest services that the highway officials in metropolitan areas can perform, not only toward facilitating traffic movement, but toward salvaging and even enhancing the value of the metropolitan area as a whole. There would follow the further introduction, by park authorities, of the parks and playgrounds with their trees and grass, and the intelligent, unselfish and courageous zoning or re-zoning of large units of the metropolis. The result will be a better rounded community and sounder and safer distribution of traffic volumes.

R. L. MORRISON,[22] M. AM. SOC. C. E. (by letter).—One of the most outstanding items in Mr. Kettering's interesting paper is the constantly increasing maximum speed of automobiles from about 58 miles per hr in 1926 to about 87 miles per hr in 1937. This is an increase of 50% in 11 yr, and the curve is almost a straight line, with practically no indication that a top limit is even being approached.

---

[22] Prof. of Highway Eng. and Highway Transport, Univ. of Michigan, Ann Arbor, Mich.

Mr. Kettering states that "people, on the average, do not want to travel much faster than 60 miles per hr," and perhaps that is a reasonably safe speed on a good clear road in the daytime. Investigations made by the Michigan State Highway Department in 1936 showed average speeds of less than 50 miles per hr, but the fastest 15% of vehicles were driven more than 65 miles per hr and, on one route, 70 miles per hr.[23] This means that many of the drivers must have been using the entire speed capacity of their cars. Darkness slowed down this fastest 15% only 2 or 3 miles per hr although, even with good brakes and lights, they could not possibly stop before hitting a dark object on the road.

While the maximum speed of vehicles was increasing 50% between 1930 and 1937, the fatalities on rural roads (the only ones on which maximum speeds can be used) increased about 37%, and the rural night accidents increased 60 per cent.[24] The increase in automobile registrations during the same period was less than 5 per cent. A close relationship between increased speed capacity of cars and increased rural night fatalities is evident.

Mr. Kettering states that the roads "where it is necessary should be above or below the ground. * * * Crossings should be eliminated * * *," and other safety features, which he lists, should be provided. Such roads would certainly cost at least $300 000 per mile. If 10% of all motor taxes could be spent entirely on the construction of these superhighways (which is very unlikely), it would be possible to build about 300 miles per yr. Therefore, at the present rate of revenues, it would take nearly 200 yr to build the 50 000 or 60 000 miles of superhighways which are assumed to be needed. It is impossible for the writer to see how superhighways can ever make more than "a small dent" in the accident rate, assuming that they do reduce accidents where they are built.

The paper discusses two items, the vehicle and the road, both of which are constantly being improved. The cars go faster each year and the roads are gradually being changed to facilitate fast driving; but, unfortunately, there is a third factor, and a very important one. It is very doubtful whether this third factor—the driver—had any more inherent ability to handle cars at high speeds in 1937 than he had in 1926. He doubtless developed a little additional skill during that time, but most accidents are caused by lack of judgment rather than by lack of skill, and certainly there is little evidence that the judgment of the average driver has improved. In fact, the less judgment he has the faster he goes. In other words, the automotive engineers and civil engineers are constantly producing cars and roads with speed capacities more and more beyond the ability of average drivers to use them safely. Of course, this is done to meet the desires of the motorists whom they both serve.

To state the problem is much easier than to offer a solution. It can be said, however, that regardless of the responsibilities of the automotive and civil engineers, public officials have a very definite responsibility to use all reasonable methods to reduce accidents, and this is a responsibility that is very far from being met in many localities. For instance, there are scarcely more than 100 traffic engineers in the entire United States, and when a State or city does decide to have one the usual procedure is not to find and appoint an experienced traffic engineer, but to appoint to that office some engineer who has no knowledge of traffic engineering. Residence in the State or city concerned is usually considered of much greater importance than experience in the work which he is expected to do. A number of States still do not require standard driver's licenses, and, in many places, both traffic laws and their enforcement are far below what they should be.

[23] "Graduated Speed Regulations," by D. Grant Mickle, *Proceedings*, 1937 Michigan Highway Conference, pp. 14–25.

[24] "Accident Facts," 1938 Edition, pp. 28 and 36.

Although Mr. MacDonald does not make the exact statement in his paper, it seems to be his guiding principle, that highways should be built so as to be of maximum service to the motorists who use and pay for them. Maximum service to the motorist through highway improvement includes decreasing his operating costs, saving his time, and increasing his safety, comfort, and general enjoyment of travel. It also includes making new areas available to travel for recreation or for other purposes. Of course, there are many other "benefits of good roads" of a more or less incidental nature. The main problem before highway administrators is to determine how available funds should be expended in order to render maximum service to the greatest number of highway users.

Unfortunately, it is the spectacular that is likely to appeal most to the general public and to politicians in high places. One school bus is struck by a train and immediately almost a billion dollars is appropriated for railway grade separations, although the same sum of money spent for such things as crossing gates, better street-lighting, the flood-lighting of street obstructions, and more efficient policing would probably save a vastly greater number of lives. Other billions are proposed for building four or six-lane roads across the deserts to accommodate a largely imaginary coast-to-coast or border-to-border traffic although millions of dollars are wasted annually by motorists traveling over untreated gravel roads and poor earth roads, and in crawling through congested city streets for the lack of by-passes around the cities.

Broad vision of future needs is required for real progress in any field, but it is possible that sound economics is more needed than dreams and visions in planning highway improvements for the next few years. Perhaps the greatest need of all is a determination of what constitutes sound highway economics. Even in that field there seems to be a great temptation to pile up vast imaginary savings. This is done by taking the difference in operating costs over pavements and over earth roads and assuming that every mile operated on a pavement results in this saving. This involves the assumption, of course, that all the millions of vehicles now using pavements would be traveling on earth roads if the pavements were not there, which seems palpably absurd. If these imaginary savings could be used to finance the super-highways on the desert all would be well.

The very real savings that can be made to present highway users through sound improvements justify the kind of road-building program outlined by Mr. MacDonald.

ROY F. BESSEY,[25] M. AM. SOC. C. E. (by letter).—This Symposium is thought-provoking, timely, and valuable. The flattening out of motor vehicle curves shown by Mr. Kettering does not indicate the end of the great national task of modern highway building, but rather the transition from the era of pioneer construction to the era of reconstruction, readjustment, and improvement for greater efficiency, safety, and beauty.

---

[25] Consultant, National Resources Committee, Pacific Northwest Regional Planning Comm., Portland, Ore.

Those responsible for highway design and construction have done an excellent job under difficult conditions, trying to keep pace with very rapidly developing or changing needs—with the growth of population, cities, industry, commerce, distribution, and technics, and, particularly, with the mushroom expansion of the automotive industry in both technics and production. In their thinking, many of those responsible have done much better than keep pace with public opinion in appreciation of many important requirements—and, consequently, have been far ahead of adequate public financial support in meeting conditions.

Although a great national network of good roads has been created, it may be concluded that transition from the pioneer stage of motor highway development is still under way. Advances in technology generally, and particularly in the field of automotive equipment; increasing density, diversity, volume and speed of traffic; and growing needs in safety, convenience, comfort, time-saving, and recreation—all call for further, probably radical, improvements in highway design and construction.

The pressures upon highway design and construction have been so great until recent years that there has been little time and means for refinement; but the present is none too soon to complete a new estimate of the situation—to re-evaluate needs and practices and to overhaul standards and plans. For this work the current nation-wide highway-planning survey is providing the essential data.

A number of desirable changes and adjustments are indicated in the Symposium. More will be disclosed by the analyses of the planning survey. Others will be found in city, metropolitan, county, district, State, regional, and national planning studies. Obviously, highway plans will have to be adjusted: *(a)* To the shifts of population and industries out of the centers of cities; *(b)* to other changes in population and industrial patterns; *(c)* to changing land use; *(d)* to activities relating to the conservation or exploitation of natural and economic resources (including flood and erosion control); *(e)* to other means of transportation (including rapid transit); and *(f)* to various other physical, economic, and social changes.

Obviously, too, it will be desirable to transfer some of the emphasis in highway design and construction from questions, such as line, grade, and pavement, in which the art is relatively far advanced, to others, such as surface, lighting, parking, rights of way, and roadsides, which (perhaps unavoidably) have had less attention in the past. All the latter features are increasingly becoming of importance to highway efficiency and safety. Wide rights of way and suitable roadside control will be particularly important factors in delaying absolescense.

From a regional planning viewpoint, the new highway era seems very definitely to involve three outstanding problems and programs:

(1) Trunk highway systems—modernization;

(2) Secondary road systems—more complete co-ordination with such resources and facilities as forests, recreational areas, mineral areas, present and probable future land use, schools, etc.; and,

(3) Co-ordinated transportation—establishment of more adequate relationships of one means of transportation with another, and with the entire system.

Requirements for trunk highway modernization will vary considerably (with geographical location, density of population, kind of traffic, etc.); but there are many requirements common to various conditions, such, for example, as location, alignment, grade, roadway and pavement standards to permit fast and continuous travel; freedom from the threats to movement; the safety and convenience involved in too-frequent crossings and points of ingress and egress, in roadway or roadside parking, in improper or excessive roadside use and obstruction, in conflicts with city and town congestions; provision for pedestrians; and provision for parking on sites away from the roadway. Fortunately, an outstanding requirement of recreational highways—the control of roadsides from the aesthetic standpoint—harmonizes generally with the requirements of commercial traffic and involves broad economic values as well.

The "freeway" or "limited motorway," with its wide rights of way, separation of opposing traffic lanes, grade separations, rotary intersections, border controls, limited points of access, etc., seems to provide the general solution and to indicate the directions in which the most effective improvements can be made in trunk highways.

A very intimate connection between highway-planning and land-use inventories and plans would seem to be the key to the most rational and efficient development of secondary road systems.

The advantages of co-ordinated transportation need not be elaborated. Not the least is elimination of much of uneconomic or needless duplication and competition. Some of the directions for study and planning of co-ordinating features in the highway field might be exemplified: Feeder lines for railroads, rapid transit lines, waterways, ports; integrated terminal facilities; interchangeable freight bodies or containers; roadside emergency airplane landing fields; and arterial express highways co-ordinated with airport locations.

In passing into the new era of automotive transport, a higher degree of co-operation is essential. Now that some of the urgencies of the pioneer period have diminished, it is to be assumed that close co-operation is more practicable. Of course, this co-operation must be based upon a mutual willingness to strive to keep design in automotive equipment and design in highways in close harmony. A closer co-operation is also required as to highway location, design, construction, and operation between various levels of government, between adjoining governmental jurisdictions, and between those responsible for highways and those concerned with other means of transportation.

Finally, if broad highway planning is to reach maximum practicable rationality and effectiveness, quickly, it should be very closely related to national, regional, State and local planning programs, and to functional planning in such fields as land use, zoning, industrial location, transportation, resource development, and recreation. Of course, the comprehensive highway planning work will be reciprocally valuable in the general planning programs.

BRUCE D. GREENSHIELDS,[26] **ASSOC. M. AM. SOC. C. E.** (by letter).—The least understood but perhaps the most important problem of motor transportation is that of harmonizing highway construction and motor-vehicle design with human behavior.

The engineer has been building highways for hundreds of years. He has learned how to deal with inanimate materials and forces that behave in a definite manner under given conditions. Human nature seems perverse and is so uncertain that the engineer, having correctly designed a highway from a mechanical standpoint, is inclined to let the "fools" kill themselves if they insist upon it.

Whatever his inclination, however, the engineer must accept the fact that the people who use the highways pay for them and, therefore, have a right to demand that they be safe. Each driver should be held to account for his own mistakes, but he must be protected from the mistakes of his neighbors on the road.

Mr. Kettering states, in the "Synopsis," that "the vehicle and the road must form a complete transportation system" and that "each one is dependent upon the other for the success of the whole." The writer would add that the whole must include the driver. Not only is highway safety dependent upon the driver's ability, but its utility is limited by his whims and desires. One loitering motorist may hold up a long line of vehicles.

There is ample evidence that drivers are foolhardy. Recently the daily press,[27] quoting from a pamphlet issued by the Board of Railway Commissioners of Canada, asks why so many people risk their lives by trying to beat the train to the crossing:

> "The latest safety devices and cautionary signals may be in operation, yet to a strange element of humanity these appear to present only a challenge.
>
> "A summary of the dangerous practices at railway crossings only adds to the wonderment as to why many drivers behave as they do: of all the accidents and near accidents reported (350 drivers and pedestrians in 6 months) 22.3 per cent of offenders ran into lowered gates, 18 per cent crossed in front of approaching trains, 11.7 per cent drove under gates while being lowered, while the remainder resorted to utterly foolish ways of risking their lives."

The people who deliberately commit suicide on the highway are few indeed. The explanation lies in another direction. One reason is that the driver or the pedestrian does not know the risk he is taking. Statistics show that a large percentage of injured pedestrians do not drive cars. They put undue trust in the ability of the driver to see a pedestrian and to bring a car under control. If one's attention is momentarily distracted he may not see something that is otherwise perfectly obvious. Every one has had such an experience.

---

[26] Associate Prof. of Civ. Eng., School of Technology, Coll. of the City of New York, New York, N. Y.

[27] *The Kansas City Times*, August 8, 1938.

The driver has had little more than a generation within which to learn to avoid the unnatural hazards of high-speed cars and to adjust himself to the unnatural experience of driving.

Professor Yandell Henderson speaking before the National Academy of Science, at Charlottesville, Va., in November, 1935, stated that:

> "'The car went out of control' is a usual explanation of automobile fatalities, but in reality, it is the driver who goes out of control. He acts in the only manner that his nature permits, the manner in which every human being always instinctively acts and always will act under the circumstances."

Any motorist, no matter how experienced, according to Professor Henderson, when suddenly and severely jolted, instinctively re-acts to steady himself in his seat, and in doing so, presses his foot down on the accelerator pedal. The more he bumps along the harder his foot presses and the more rigidly he grasps the wheel. People cannot be changed but motor cars can. Professor Henderson would have a pedal under the left foot which would counteract the effect of the right by shutting off the power.

There are many phases of behavior—physical, mental, and emotional—that need to be considered, but obviously only a few can be considered in a short discussion. One of the natural attributes most discussed in connection with automobile driving is that of "reaction-time." This is the brief interval between the happening of something in one's environment and the time when a certain response is made to it. This interval may be, for example, that between the time a pedestrian steps into the street and the time the brake is applied to avoid hitting him.

In general, the speed of all forms of reaction varies from one person to another and from time to time in the same person. Extreme fatigue decreases the ability to respond. Emotions such as fear or anger interfere with the driver's reactions. The effect of alcohol varies with the individual—it does not necessarily lengthen reaction-time, but an excess amount makes the reaction-time more uncertain. The reaction to hearing is quicker than to sight.[28]

Certain responses are made more quickly than others. The hand is quicker than the foot. Perhaps a hand-operated brake would be better in an emergency.

Although reaction-time has been considered mainly in connection with highway safety, a means for reducing it is probably more important in highway design than in safety work because it has not been demonstrated that reducing reaction-time would lessen accidents. On the other hand, it would speed up traffic and increase highway capacity.

Persons who react more quickly drive at higher speeds. They thus void whatever advantage their quickness gives them and have just as many accidents as slower drivers.[29] The average minimum spacing between vehicles depends upon the reaction-time of the individual drivers. The spacing between vehicles fixes the number that can occupy any length of roadway and, hence, is one of the factors determining highway capacity.[30]

---

[28] "Reaction-Time and Traffic Behavior," by Bruce D. Greenshields, *Civil Engineering*, June, 1937, p. 384.

[29] "A Study of Factors Influenced by Automobile Brake-Reaction Time," by Frank R. Olmstead, *Proceedings*, 22d Annual Highway Conference, Ann Arbor, Mich.

Earl Allgaier, Safety and Traffic Engineer of the American Automobile Association, after subjecting approximately 22 000 drivers to a battery of 15 tests, states that driving ability reaches a maximum at about 25 yr of age.[31] The decline begins between 40 and 50 yr and grows rapidly from that point on. The tests included field of vision, eye dominance, excitability, blood pressure, hearing, and steering ability. Mr. Allgaier states that the falling off in the test scores made by drivers more than 40 to 50 yr of age need not necessarily indicate that these drivers are actually poorer or less safe than younger drivers. They are more experienced and likely to be more cautious.

Dr. H. M. Johnson, referring to such tests, states that he has found no published report of a comparison which warrants the conclusion that test performance is closely associated with accident rate.[32]

Dr. A. R. Lauer, of Iowa State College, who has developed many of the tests, states[33] that after having analyzed several sets of data it is his guess that "when our final analysis is made we will find no high validity coefficient." He adds as a reason the fact that "human nature is unstable and highway conditions are highly variable." There is significance for the highway designer in the last statement. Human nature cannot be changed but highway conditions can be made less variable.

To claim that human nature cannot be changed does not mean that one cannot learn to do things better or that natural handicaps cannot be overcome. The quickness with which one can move his foot in a certain way in response to a given stimulus cannot be reduced by practice beyond a certain point; but by simplifying the movement required to control the vehicle the car manufacturer can, in effect, shorten the reaction time. Although there is a natural limitation to one's ability to see, cars can be made easier to see out of and highway signs can be improved by an increase in size or by illumination.

The experienced driver has learned to make the proper responses to a large number of situations. He is less likely to be surprised. Experience enables one to make quicker judgments. Judgment is more complex than perception. For example, in taking a laboratory test of brake reaction-time, a light is flashed and the subject presses the brake pedal. He perceives the signal and acts. No judgment is involved. He has decided what to do beforehand. In the case of passing a vehicle on the road, he first sees the vehicle approaching on the opposite lane. He then decides whether he can pass the car ahead. This deciding is a matter of judgment and is a much more complex process than "sensation." It may take minutes instead of seconds.

The young driver cannot be given experience but experience can be made less necessary by simplifying the highways and by informing the motorist of approaching conditions so that he has time to decide what to do.

[30] "Studying Traffic Capacity by New Methods," by Bruce D. Greenshields, *Civil Engineering*, May, 1935, p. 301.

[31] *Public Safety*, May, 1938.

[32] "The Detection of Accident-Prone Drivers," *Proceedings*, Highway Research Board, 1937, p. 445.

[33] *Loc. cit.*, p. 452.

Consider highway curves, for example; in most States all curves are heralded by the same type of sign. The driver does not know whether the curve is sharp or flat or whether he can drive it at 50 miles per hr or whether he should slow to 20 miles per hr. Why not give the motorist the information he needs?

Common arguments against such a practice are that the safe speed for one car is not that for another car and that the State would be to blame if a defective or old-model car had an accident while traveling at the announced speed. The curves should be designated by numbers as 1, 2, 3, etc., to indicate riding qualities. The motorist would soon learn at what speed his car would take a No. 1 or a No. 2 curve.

Adequate highway signs might have prevented two fatal accidents that occurred at Fidelity Corner, six miles south of Carthage, Mo., in August, 1938. In the writer's opinion the rather inconspicuous "Slow" sign, followed by another indicating the intersection, should be replaced by (1) a prominent intersection sign, and (2) a danger sign; and, to make sure, a "blinker" should be added. Note that, first, the driver would be informed of what to expect; and, second, would be warned of danger.

Highways must not be deceptive. Many a new highway has failed to reduce accidents. Its deceptive appearance of safety has induced motorists to step up their speed to a point at which they did not have time to react to the road's surprises.

Speaking on the subject of "Highway Design and Safety" at the Highway Safety Conference, Yale University, on April 4, 1938, Guy Kelsey, of the Signal Service Corporation, Elizabeth, N. J., described the surprise hazards confronting drivers operating on 5.4 miles of a "very modern highway" selected at random. Low visibility, head-on-intersection-of-vehicle hazards, as well as several traffic flow inefficiencies were among the deficiencies found in the short stretch.

The statement is made by Mr. A. R. Nichols[34] that even if the safety and utilitarian requirements have been met, the road that does not closely follow the lay of the land results often in glaring artificiality of ugly cuts, high fills, and an increased area of destruction of natural vegetation. Such unnecessary artificiality makes a road more dangerous. Its unnaturalness leads to surprises.

Although the unexpectedness in human nature cannot be removed like the perplexities of the highway there is the gratifying fact that human nature *en masse* is not so variable after all. Insurance companies cannot tell how long any individual will live, but they have built up a thriving business on predicting how long the individuals in a large group will live.

From his studies of behavior on the highway (such as the spacings maintained between vehicles, the distance required for passing, and the point at which drivers slow down because there is a vehicle ahead) the writer has arrived at the definite conclusion that drivers do behave in a definite manner under certain conditions. The curves resulting from the plotting of such data are surprisingly smooth.

The traffic engineer must study human nature as the design engineer has studied soils and concrete and steel. Road intersections that are unsafe must be compared with those that are safe to find out how they differ. The "specifics" of driving behavior must be determined by careful analysis. How prominent must a sign be for the driver with poor eyesight to see it? Advertising signs are much more prominent than highway signs. At what distance can one determine whether or not an object is moving? These are the facts the motorist needs to know, and does not.

---

[34] "Highway Design: Its Relation to Landscape Objectives," by A. R. Nichols, *Proceedings*, Highway Research Board, 1937, pp. 269–278.

The highway of the future must expedite traffic and it must do it safely. It must be honest. If it invites speed it must have no dangerous surprises. As sight distances are increased and vehicles are made even more responsive to control, speeds will go up in direct proportion. If 50 miles is a high average speed now it is because drivers feel comfortable and safe at that speed. If average speeds of 100 miles per hour are adopted in the future it will be because the driver feels safe at that speed. When speeds on limited ways go high enough they will be restricted to the best drivers.

It is hoped that these remarks have added something to the excellent papers of the Symposium by emphasizing the importance of studying the highway user.

ROBERT B. BROOKS,[35] M. AM. SOC. C. E. (by letter).—In the final analysis, the place of the express highway in a modern road system must be determined by its economic justification.

The most important economic phase of the paper by Mr. MacDonald is that in relation to the continued construction of super-highways. His idea is that present policies indicate that the location of super-highways will be integrated with population centers and that the layout will not be on the transcontinental basis.

It is undoubtedly true that in Germany and Italy the express highways are built for protection and aggression as well as for peace-time traffic. In the United States express highways are built to satisfy the demand of peace-time traffic, as well as to provide highways that can be used for handling men and equipment in time of war. This protection did not exist twenty years ago, as was shown definitely, time after time, by the wrecking of highways by even limited troop movements during the World War. There can be no doubt that there is a definite place for the express highway in a modern road system.

In January, 1932, the United States had a total of 3 790 miles of extra-wide highways in its State systems and not included in the mileage of city streets and parkways.[36] By extra-wide highways are meant those having more than two lanes. There were 2 230 miles of three-lane width, 1 385 miles of four-lane width, and 175 miles of five-lane width and greater.

Five years later, and bringing this date up to July 1, 1937, there is a total of 7 999 miles of important highways exceeding two-lane width, of which 4 703 are three-lane, 3 096 miles are four lane, and 201 miles are five and six-lane.[37] This increase in width is significant of the trend in highway construction. Within that same time the genuine planning of modern highway systems has been given exhaustive study, under the basic assumption that they should be planned to do the greatest good for the greatest number.

---

[35] Cons. Engr., St. Louis, Mo.

[36] *Public Roads*, November, 1932.

[37] *American Highways*, July, 1937.

State traffic surveys should reveal not only the traffic volumes, and other physical information, but should include a description of financial status and explanations of how the citizens are to pay for highways in the future. Consider Missouri, for example. The total mileage of all the roads in the State is 104 850. The State highway system, as now designated, contains a total of 17 193 miles. Of this total there are 1 651 miles in the primary system, 5 877 miles in the secondary system, and the remainder in the supplementary system with its traffic relief, park connections, etc. In other words, the State highway system in Missouri specifically consists of 16.4% of the total road mileage in the State which, however, does carry more than three-fourths of all the traffic when measured in vehicle-miles per year. Carrying this computation a step further, the several systems of highways in Missouri, in the survey report of 1934, showed the following percentages of traffic:

System	Highway mileage	Vehicle mileage
United States highways	3.6	48.1
State highways	4.6	18.5
Supplementary	4.1	8.0
County roads	87.7	25.4
Total	100.0	100.0

Although proper consideration must be given to the farm-to-market roads and to the secondary road system, it is readily apparent that the main highways carry by far the greater volumes of traffic. This is as true in other States as it is in Missouri.

The era of toll roads in the United States is passed. Although individual experiences may warrant the impression that the user would be willing to pay an extra sum for using express highways between centers of population, the cold facts are that there are not enough motorists to amortize the cost of building an express highway in the United States. This is proved by the fact that most motorists will drive many miles out of their way to avoid paying even a small toll on a bridge which might otherwise save them considerable time as well as the price of the bridge fare.

If the cost of the express highway is to come from gasoline tax and vehicle license fees, with added grants from the Federal Government, engineers must "cut the coat to fit the cloth," and in so doing build express highways in such a way that they will handle those traffic volumes in, around, and near metropolitan areas where the expense of construction can be justified, not only from an engineering standpoint but from that of public opinion.

With the proceeds of most of the State bond issues for road purposes already spent, road programs seem to be on a "pay-as-you-go" basis. This means a further economic justification rather than a lavish expenditure to take care of anticipated needs.

Highways are often called traffic arteries through which streams of automobiles flow. The comparison, of course, is to that most perfect system of veins and arteries which takes care of the circulation of the blood. Comparing traffic flow to the distribution of water, the largest pipes are next to the source of supply, or reservoir. As the water is carried to various sections, the sizes of the pipes are lessened in deference to the demand for water by the consumers. The system of arteries and veins in the human body shows very definitely that the need for the larger arteries and the larger veins is near the heart, and the size of each is smaller and smaller as it gets away from those parts of the body that need circulation least.

It is self-evident that the pressure of traffic is from the centers of congestion in metropolitan areas outwardly, just as water is distributed from a reservoir, and just as blood is circulated in the body of an individual.

"Flow" maps invariably show that traffic demands wider traffic-ways near centers of population. The same maps also show that the two-lane highways are sufficient to take care of traffic needs a reasonable number of miles away.

Although the out-of-State farmer can see no reason why his gas tax money should go for the building of an express highway from Chicago, Ill., to another locality, neither does the urban dweller see any reason why his tax money and that of his neighbors in the large city, which may pay three-fourths of the entire cost of constructing highways in the State, must be used in building farm-to-market roads which he, the urban dweller, may never use.

The opinion has been expressed that large cities must construct express highways in order to exist. The writer believes that various State traffic surveys will supply the factual data which will educate every one, whether urban or rural dwellers, as to the mutuality of traffic needs so that gas taxes and vehicle license fees can be spent on a network of traffic arteries, which will take all classes of roads into consideration.

During the eight years, 1925–1933, a definite system of streets was laid out in the City of St. Louis, Mo. These streets were divided roughly into three classes: 60-ft streets, 80-ft streets, and 100-ft streets. A progressive system of construction each year saw various sections completed, so that to-day with the street plan practically completed, traffic flow maps show, definitely, the value of the various widths of streets. Consider the planned design of what is known as US 40TR, in Missouri, which extends from St. Louis westward about 40 miles to Wentzville, Mo. It is a two-lane highway from Wentzville to the Missouri River; a three-lane highway from that point to Chesterfield; a four-lane contiguous highway from Chesterfield to Bellefontaine; and then 2 two-lane highways divided by a 30-ft parkway to a point close to the City of St. Louis. At this point it is necessary to converge into a subway running three miles inside the city limits to Vandeventer Avenue, where traffic is then poured into two or three streams for distribution.

Through bitter experience highway engineers in Missouri have already learned how costly it is to obtain right of way sufficiently large for an express highway. The longer the acquisition of land is delayed, the more it will cost. Therefore, on express highways they have, and are, securing a 200-ft right of way which will take care of future traffic needs, although the present-day construction of extra-wide highways may not be warranted at the present time.

Although many engineers would like to see the general acceptance of four-lane highways instead of two lanes, it seems self-evident that there is not economic justification for such an expenditure in many cases, and, although there may be some accidents caused by a third lane, the three-lane traffic is a transition from a two-lane highway to the express highway. Any one who doubts this point should note the immediate relief afforded when driving in holiday traffic on a two-lane highway almost at the moment it passes into a three-lane highway.

State traffic surveys now being completed and analyzed will show where express highways should be located and, although there may not be economic justification for the construction of an express highway now, it certainly is good planning to acquire land for the subsequent building of these roads when, if, and as, the need arises.

At its meeting in July, 1937, the members of the Missouri State Highway Commission were sufficiently impressed with this idea on U. S. Route 54, between Jefferson City, Mo., and the Lake of the Ozarks, that they instructed the Engineering Department to arrange for the acquisition of sufficient right of way to provide for the building of an express highway of extra width sometime in the future. At present, only a two-lane highway, leading south from Jefferson City for a few miles, will be constructed. Missouri needs express highways to take care of the outward pressure of traffic from its large cities. The writer cannot agree that there is a need for express highways up and down the land where the traffic itself cannot show an economic justification. He does agree most emphatically that engineers must plan wisely to secure sufficient right of way in order to add more lanes to take care of future traffic demands.

Mr. R. E. Toms, Chief, Division of Design, U. S. Bureau of Public Roads, recently presented data to demonstrate that from 95% to 97% of the State highway mileage in the United States may never progress in improvement beyond a two-lane highway.[38] If it is desirable to improve such a small percentage of the highway system as express highways, then let it be realized from the standpoint of economic justification, that the function of an express highway in a modern road system is to take care of the outward pressure of traffic from metropolitan areas to the extent that this extra pressure exists, and not as a continuous super-highway connecting centers of population.

If any further evidence is needed to show that the location of super-highways should be integrated with respect to population centers and that their layout should not be on a transcontinental basis, it is only necessary to observe the restricted use of the State and Federal highways immediately outside the orbit of metropolitan areas as ably shown by Mr. MacDonald.

H. GEORGE ALTVATER,[39] ASSOC. M. AM. SOC. C. E. (by letter).—Referring to "Trunk-Line Highways in Metropolitan Areas," Mr. Smith states that highways must serve the area as trunk lines for public utilities and that inadequacy of right of way will affect the utilities. The practise of laying pipes beneath the traveled roadways of streets was inaugurated in the days of horse-drawn wagons on dirt roads, and then it caused little inconvenience in digging up the streets. With the carefully designed pavement of to-day, however, there is no reason why each block of it must be repeatedly trenched through and patched numerous times during its life.

---

[38] *American Highways*, January, 1937, p. 12.

[39] Cons. Engr., Denver, Colo.

At the time of the World War, the United States found itself so thoroughly unprepared to supply munitions that the only experienced engineering organization in the nation that was qualified to build explosives plants could undertake to build only about one-half the necessary capacity, and the remainder was built by entirely new inexperienced organizations. Under these circumstances, the matter of utilities in streets was a serious cause of delay. The main plant transportation, at Nitro, near Charleston, W. Va., where one of the two American smokeless powder plants was constructed, consisted of 45 miles of narrow-gage railroad, which was responsible for the results obtained. In the deep mud the tractors and even horses became bogged down, so that oxen were resorted to for moving heavy machinery. It was not possible to build roads first because the streets were torn up for utilities.

There were untreated industrial water lines, treated domestic water lines, high pressure fire lines, steam lines, industrial sewer lines, domestic sewer lines, storm sewer lines, gas lines, electric power lines, telephone and telegraph lines, sulfuric acid lines, nitric acid lines, caustic soda lines, ether lines, and alcohol lines. Their construction in the streets obstructed the delivery of essential machinery. Time was the only consideration, because in July, 1918, the Allied Armies were using explosives about six times as fast as they could be produced by all plants. The separation of rights of way for utilities would have permitted road construction to be done previously or concurrently. The writer recommends to industrial city planning engineers that an attempt be made to provide separate rights of way for utilities on new developments.

This is in no way a reflection upon the excellent work of those who were responsible for the miraculous speed in the construction of the plant at Nitro, because they produced their $75 000 000 job in about the same time as the slightly larger Nashville (Tenn.) job was done by the explosives specialists.

Although the presence of utilities in streets contributes greatly to the engineering difficulty and cost of subways in the large cities there does not seem to be any feasible way to avoid it; but in new developments where land is relatively cheaper a separation of the utilities in the rights of way should be possible.

W. W. Crosby,[40] M. Am. Soc. C. E. (by letter).—The conclusion of Mr. Kettering's "salmon" story is good, and his remarks on "where to get the money," should be regarded as fundamental. Although the writer could applaud most, if not all, the remainder of Mr. Kettering's remarks, it is from the ideas just mentioned that he wishes to propose an hypothesis which may account for many of the defects in the highways of the United States as well as suggest an answer to an engineering question that has been widely discussed for years.

---

[40] Cons. Engr., Coronado, Calif.

Before so doing let the writer note that he has carefully read the paper by Mr. MacDonald, which seems to express, fairly, the attitude of the U. S. Bureau of Public Roads for the past fifteen years. A significant quotation (regardless of the question of fact) in this case is "Highway builders [in the United States] are proceeding on the principle that the utilization of the highways must produce directly the revenues with which to finance their construction" (see heading "Super-Highways").

The third paper of the Symposium, although limited to a narrower field, seems commendably broad in conception. Mr. Smith remarks several times on the fundamental importance of adequate rights of way, which the writer has been emphasizing for years. Mr. MacDonald barely suggests anything on this point although its prompt recognition is even more important in his work outside the cities. In some of its recent publications[41] the writer believes that the Bureau of Public Roads has admitted the need for "elbow room"[42] in the future.

The writer believes with Mr. Kettering that "Sometimes, people calculate entirely too much in dollars," particularly in setting up ideals—that is, in planning. Often it is necessary for the material approach to ideals and standards to be gradual as funds may be found; but to establish standards on the basis of funds in sight only results in regrets.

This brings the writer to the hypothesis mentioned:

May it not be that an answer to the questions discussed for so many years—"What is the matter with engineering?" and "Why does it not rank with the learned professions?"—lies in the fact that too many of its more prominent representatives cling to the definition of an engineer as one who "can make one dollar do the work of two," and are not imbued with the spirit of one familiar to the Society: "An engineer is one who adapts the forces of nature (including Human Nature) to the benefit of mankind," or perhaps the latest one:[43]

> "An Engineer is one who, through application of his knowledge of mathematics, the physical and biological sciences and economics and with aid, further, from results obtained through observation, experience, scientific discovery and invention, so utilizes the materials and directs the forces of nature that they are made to operate to the benefit of society. An Engineer differs from the technologist in that he must concern himself with the organizational, economic, and managerial aspects as well as the technical aspects of his work."

THOMAS H. MACDONALD,[44] ESQ. (by letter).—The last paragraph of the paper emphasizes the fact "that the country has completed the pioneer stage of road development and every trend of highway development of the future must be an intelligent meeting of the particular service to be rendered." In order that there may be an intelligent meeting of the particular service to be rendered in the highway development of the future, it is essential that all pertinent factual information be available to highway engineers and adminis-

trators. In the paper reference was made to the State-wide Highway Planning Surveys. These are now (1939) being conducted co-operatively between the Bureau of Public Roads and 46 States and the Territory of Hawaii. Already these surveys have produced the factual basis for the solution of specific highway problems within a single State. They have also formed the basis for a comprehensive report from the U. S. Bureau of Public Roads, submitted to the Congress of the United States on April 27, 1939, by Special Message from the President of the United States. This report[45] was made in compliance with the specific direction of the Congress and consisted of two parts—Part I covering the "Feasibility of a System of Transcontinental Toll Roads," and Part II covering "Master Plans for Free Highway Development."

From the factual information developed in the State-wide Planning Surveys and other specific studies developed by the Bureau of Public Roads and the State highway departments, the definite conclusion was reached, and the recommendation made to the Congress, that it was not feasible to construct a system of transcontinental toll roads—three east and west, and three north and south—with any expectation of such a system serving the genuine traffic needs of the United States, or of being self-liquidating. The facts and considerations leading up to this conclusion were fully discussed in the report.

Further analysis and study of the Planning Survey data clearly indicate the problems confronting highway engineers and administrators. Some of them are of long standing and have become acute through the tremendous increase in highway traffic. Not only increased numbers but also increase in normal speeds critically affects the various problems.

Much of the yearly obsolescence of the rural highways built in the past has been due to the restrictions imposed upon the design by inadequate rights of way. Another outstanding problem centers around the metropolitan areas and involves the provision of means for getting into, around, and through such areas without the delay that is involved in using present inadequate facilities. Traffic-flow maps indicate the natural flow lines between the various regions of the United States. A limited system of inter-regional highways approximating 1% of the total highway mileage constructed to modern standards is needed to provide adequately for the ever-growing traffic. Further study is needed to determine the location and approximate mileage in each State of such a system.

From a full discussion of these problems, there emerges the general outline of a master highway plan for the entire nation. The prosecution of the plan in all its parts calls for appropriate action by the Federal and State Governments and all county and municipal subdivisions. As desirable joint contributions of the Federal and State Governments, the report lists several undertakings as follows:

(1) The construction of a special, tentatively defined system of direct inter-regional highways, with all necessary connections through and around cities, designed to meet the requirements of the national defense in time of war and the needs of a growing peace-time traffic of longer range;

(2) The modernization of the Federal-aid highway system;

---

[45] H. R. Doc. No. 272, 76th Cong., 1st Session.

(3) The elimination of hazards at railroad grade crossings;

(4) An improvement of secondary and feeder roads, properly integrated with land-use programs;

(5) The creation of a Federal Land Authority empowered to acquire, hold, sell, and lease lands needed for public purposes and to acquire and sell excess lands for the purpose of recoupment.

The report emphasizes the difficulties encountered in the acquisition of adequate rights of way; and, in view of the fundamental necessity of such rights of way, proposes definite measures by which the United States could aid in the acquisition of suitable rights of way and simultaneously contribute helpfully to the solution of other urgent problems, especially certain problems confronting the larger cities.

Leroy C. Smith,[46] M. Am. Soc. C. E. (by letter).—With the ever increasing use of the passenger automobile, together with the increased use of motor trucks for industrial transportation, the necessity for adequate highway systems in and about the metropolitan areas is becoming more and more acute. The problem has reached such proportions that the Federal Government has taken definite steps to develop a system of inter-city super-highways, connecting the major metropolitan centers, and are contemplating acquiring such widths of right of way that even the most enthusiastic planners of the past had not ventured to advocate. The Government plans, discussed for connecting major metropolitan centers, provide for right-of-way widths ranging from 200 ft to ¼ mile, many of them being parallel to railroad lines. Although these roads will alleviate the condition between the centers, there must be a system of express highways within the metropolitan centers to be connected with the inter-city roads.

Industrial Super-Highway Development in the Detroit Area.—Many of the civic and industrial leaders of Metropolitan Detroit and Wayne County are proposing a system of cross-town highways to permit the free flow, not only of the passenger motor traffic but also the large volume of industrial traffic. Factories of all types and descriptions are scattered over Wayne County and they depend upon co-ordination with one another in the process of their manufacturing operations. This is particularly true of the automobile industry where parts, bodies, etc. must be brought to the assembly plants. Narrow streets and roads not only delay transportation to the plants but create a dangerous situation with respect to other vehicles. These conditions could be eliminated by a system of wide thoroughfares. The "Drive Away" system of transporting new automobiles is another factor that creates congestion on the highways in the metropolitan areas as well as on the inter-city rural highways. Adequate facilities for delivering new automobiles would result in savings in transportation costs, thereby reducing the cost of new vehicles and encouraging new car buying.

Public Reaction.—Public reaction continues to be toward rapid transportation on rubber. A large majority of people are pleased to use their automobiles in lieu of buses or street cars in spite of the fact that transportation costs may be a little greater. This fact must be recognized and encouraged by the public agencies—whether local, State, or Federal—who are in charge of highway development. In 1938, the people of the State of Michigan adopted, by the vote of a great majority, a constitutional amendment which specifically provides that highway revenues be used for highway purposes only. This is another indication of public reaction to highways. Wayne County, in which Detroit is situated, has no property tax for highways. The only funds accruing to the County for highway construction and development are from the motor-vehicle gas and weight tax revenues. This is general throughout the State of Michigan. The constitutional amendment, however, guarantees that there shall be no diversion of highway funds for purposes other than highway construction and development.

---

[46] Chf. County Highway Engr., Wayne County Road Commrs., Detroit, Mich.

Huron-Clinton Parkway.—The Legislature of the State of Michigan has enacted a law providing for the incorporation of the Huron-Clinton Metropolitan Authority. The purpose of this act is to permit the planning, development, and construction of parkways and limited access highways through two to five contiguous counties in the valley of the Huron and Clinton rivers. The act is comprehensive and is well worth detailed study.

Conclusion.—All State agencies are in accord with the Federal plans for cross-country highways. As in all cases of development, however, the question of adequate funds for such development always seems to be the chief obstacle. With a program of feasible and economical financing, there is no reason why these plans cannot be effected in the near future. The United States needs highways and, in line with the provisions of the Federal Constitution, there should be free intercourse between the cities and States of the country.

Paper No. 2048

RECONSTRUCTION OF A PIER IN BOSTON, MASSACHUSETTS, HARBOR

By Charles M. Spofford,[1] M. Am. Soc. C. E.

With Discussion by Messrs. William G. Atwood, John N. Ferguson, John Ayer, and Charles M. Spofford.

Synopsis

The reconstruction of the outer parts of a large ocean pier, the wooden pile foundations of which had been seriously damaged by marine borers, is described in this paper. The wooden piles were removed and steel bearing piles many of which had a length in excess of 100 ft were substituted. These are believed to be the longest steel bearing piles ever used. They were driven by steam hammer through fill and blue clay to a bearing on bed-rock, or the hard material immediately overlying it. The piles were placed in groups of four with the upper ends protected by steel cylindrical caissons filled with concrete.

For the most part, the concrete deck of the old structure and its supporting concrete beams were removed and replaced by a new concrete deck supported on steel beams and girders. A test was made on a pile having a length of 137 ft, and the complete data of the test are given. As far as the writer is aware no other test on a pile of this length has been reported previously.

The use, in certain parts of the pier, of a light-weight concrete to protect the wooden piles from further damage is also described.

General

The control of the water-front of Massachusetts is under the direction of the Massachusetts Department of Public Works which is administered by one commissioner and two associate commissioners. Among the duties of the Department are the construction, maintenance, and operation of State piers located at various points along the Massachusetts seacoast, the largest of which is Commonwealth Pier No. 5, in South Boston.

Note.—Presented at the meeting of the Waterways Div., Boston, Mass., October 7, 1937, and published in October, 1938, *Proceedings*.

[1] Hayward Prof. of Civ. Eng., Mass. Inst. Tech., Cambridge, Mass.; Cons. Engr. (Fay, Spofford & Thorndike), Boston, Mass.

Boston is one of the important ports in the United States, its standing on the Atlantic seaboard being exceeded (as measured by the value of its foreign and domestic commerce) only by the Ports of New York, N. Y., Philadelphia, Pa., and Baltimore, Md. Commonwealth Pier No. 5, with its transit sheds and other facilities, is the principal pier for passenger ships on the southerly side of the harbor and is used by several foreign lines, including the Italian, French, and Holland-American Lines. It is also used by the American Hawaiian and the Luckenbach Lines furnishing service to the Pacific Coast, and by the Canadian National Steamship Company operating to the West Indies. Much freight is received at Pier No. 5, wool being one of the principal products. Boston is the second largest wool port of the world, exceeded only by the Port of London, England.

The pier provides berths in excess of 1 100 ft in length, with a depth of water of at least 40 ft at mean low tide. It is sufficient in size and draft to accommodate the largest ships now in existence. Fig. 1 shows the location of this and other State piers in Boston.

HISTORICAL

The construction of the pier was begun in 1897, under the direction of the State Board of Harbor and Land Commissioners, by the building of a granite sea-wall around a site, 300 ft wide by 1 150 ft long, and the filling of the interior with material dredged from docking spaces alongside the pier. This wall was supported on spruce piles capped with spruce planks and timber. The spaces between the piles and in front of them were filled with small stone chips and gravel, except that the face of the slope in front of the wall was protected by large stones weighing 100 to 300 lb each. After the solid part of the pier had been completed, it was surrounded by a 50-ft platform of hard pine supported on oak piles. The heads of the piles were covered with coal tar applied at a temperature of not less than 120° F, but no other preservative treatment was used. The total cost of this part of the pier was not quite $400 000.

The then comparative inaccessibility of the pier by land delayed the making of satisfactory arrangements for its use. In July, 1907, a part of it was seriously damaged by fire. The pier was finally leased on November 1, 1910, together with certain land in its rear, to the Old Colony Railroad Company at the annual rate of $75 000, the lessee to pay the city taxes. This lease was not of long duration as on June 28, 1911, the Massachusetts Legislature created a board entitled "The Directors of the Port of Boston" and transferred to this board all the rights, powers, and duties of the former Board of Harbor and Land Commissioners pertaining to the Port of Boston. It also authorized the expenditure of $9 000 000. The Directors decided to build a terminal to serve large vessels and reached the conclusion that Commonwealth Pier No. 5 afforded the best opportunity for the development of such a terminal.

After months of negotiations the Directors secured from the Old Colony Railroad Company, on November 6, 1912, the control of the pier and at once set aside $2 500 000 for improvement, and work was started two days later. This improvement included dredging the berths alongside to 40 ft below mean low water; cutting off burned piles on the easterly side to Elevation + 10

and the remainder of the piles to Elevation + 14, and supporting the deck structure by concrete beams resting on the original oak piles; replacing the timber platform with a concrete deck, covering the entire pier except the outer parts of the platforms, and the outer end, with two-story non-combustible sheds supplied with facilities for handling both freight and passengers; and constructing railroad and highway connections. The pier was opened for business on May 31, 1913, when a new service of the Hamburg-American Line was instituted, the western half of the pier being assigned to this line. The Directors also agreed to furnish the White Star Line with service on the east side.

Pier improvements, as originally planned, were estimated to cost $1 250 000, but through amplifications as a pier and as a monument to advertise Boston the total sum finally expended was approximately $4 000 000.

ATTACKS BY MARINE BORERS

In 1925, the attention of the Public Works Department was called to the fact that marine borers were becoming active in Boston Harbor, and it was decided to investigate a few of the foundation piles under the platforms at Commonwealth Pier No. 5 to determine the extent of the destruction by these borers. Later examinations were made in 1932 and in 1934, and the results of all these examinations are shown in Table 1.

TABLE 1.—EFFECT OF MARINE BORERS, COMMONWEALTH PIER NO. 5

* Number of piles.

It will be seen that, in the 1925 examination, approximately 55% of the piles examined were found to be affected by marine borers, whereas in the last examination about 92% were affected. The action of the borers had been constantly increasing and, based on the results of the last examination, about 10% of the piles were one-half or more destroyed. During the last examination (Table 1(*c*)), six of the piles were found to have a diameter of not more than 3 in. at the mud line, instead of their original diameter of about 10 in.

As a result of these examinations, the Engineers of the Department recommended that studies be made of means to prevent further action by marine borers and a tentative plan for placing solid filling under the pier platforms, retained by a steel bulkhead around the pier, was developed at an estimated cost of approximately $437 000. This method had to be rejected after the nature of the subsoil was thoroughly investigated.

It is interesting to note that during reconstruction most of the piles that were examined by the divers were pulled out by the contractor, and it was possible to get a complete view of the damage. In general, the reports of the divers were found to be correct except that piles reported three-fourths gone were found to be in a worse condition than reported. Piles upon which the original bark remained in place were found to be in good condition, but wherever the bark was missing, the pile had been badly attacked by the worms. The major part of the damage was caused by *Limnoria;* some *Teredo* were found, but not in sufficient number to affect the piling seriously.

METHODS OF RECONSTRUCTION

The reconstruction may be treated conveniently under two divisions: (1) The repairs of the platforms and pile foundations of the outer parts of the pier; and (2) the repairs of the foundations of the head-house at the shoreward end of the pier.

Platforms and Pile Foundations.—Three different types of bulkhead construction were considered for this work: (*a*) An enclosure of steel sheet-piles filled with sand and gravel; (*b*) built-up "master-piles" with intermediate sheet-piles; and (*c*) the cellular type. Type (*a*) consists of driving a row of steel sheet-piles immediately outside the present face of the deck, holding the pile tops back by wales and tie-rods, with sand and gravel fill around the timber piles, thus preventing further damage to them from marine borers. With the data available from the borings and laboratory analyses described elsewhere, it was possible to make studies to determine the size and length of the steel sheet-piles necessary to withstand the pressure from the fill to be placed around them to the elevation necessary to protect them from further damage from marine borers. From these studies, it was found that due to the soft underlying clay, the piles would have to be driven to an excessive length, in order to obtain sufficient pressure at the toe to hold them in place. This was determined by computing the active earth pressure on the bulkhead by the application of the Rankine equations and equating this pressure with the resistance of the blue clay at the face of the pile corresponding to its shearing resistance. The latter was determined by tests on undisturbed samples.

The width of the wharf platform was too small to permit the sheeting to be tied back efficiently to the cross-bents supporting the wharf and the only feasible method of restraining the upper ends of the sheeting seemed to be to build a series of concrete "dead men" at a considerable distance back of the sea-wall and to tie the ends of the sheeting to these "dead men" by heavy steel tie-rods. This process would have necessitated the drilling of holes in the existing walls, a laborious, time-consuming, and expensive process.

Type (*b*) consists of the construction of "master piles" composed of heavy built-up sections placed at intervals along the front of the wharf face, and the

driving of intermediate sheet-piles between, and supported by, these built-up members. For this type of construction the master piles would have to be held at the bottom by being driven a considerable distance into the underlying clay and at the top by tie-rods fastened to concrete "dead men" as proposed for Type (*a*). The same difficulties were found in supporting this type of bulkhead at its toe as were found for the simple steel sheet-piles.

The third type (Type (*c*)) of bulkhead considered was a cellular type but, among other difficulties, it was found that the available distance between the sea-wall and the face of the existing wharf platform was insufficient to provide the necessary stability for this type of construction which would have to be built on a steep slope.

In view of the foregoing difficulties with bulkhead construction and its excessive cost, it became necessary to develop another method for this part of the work. After considerable study it was decided to use steel bearing piles driven either to bed-rock or into the hard overlying strata and to support the reinforced concrete slab by a framework of steel beams.

The following description covers this method of construction: Steel bearing piles, 14 in. by 14.5 in., weighing 89 lb per ft were driven, in clusters of four, to practical refusal into bed-rock or into hard overlying material. During driving, they were held in position laterally by timber frames. The upper parts of each group were surrounded by a structural steel cylinder filled with concrete, and concrete was deposited in the caisson above the tops of the steel piles which, in no case, were above mean low water. The piles and caissons are shown in Fig. 2.[2] For most of the work the cylinder piers thus formed were spaced 40 ft, center to center, longitudinally and 21 ft 5 in., center to center, transversely. The various steps in the construction were as follows:

(1) The rip-rap and a portion of the silt in the area in which a group of piles was to be driven were excavated to as great a depth as feasible;

(2) The steel caisson for the group of piles was generally driven by a steam hammer to a minimum depth of 5 ft in the clay subsoil with its top at the proposed level of the bottom of the new steel and concrete deck;

(3) The material within the caisson was excavated to a depth of 15 ft below the anticipated level of the tops of the piles;

(4) The four steel piles in each caisson were then driven, one by one, by a steam hammer. (Except in a few cases, all piles had to be spliced once. The minimum length of pile was 98 ft. In certain cases the piles twisted in driving and in certain cases the driving of one pile carried down another pile. Possibly these effects would have been avoided by increasing the spacing, but this would have increased the cost and added to the load carried by individual piles);

(5) A 2-ft layer of sand and gravel was deposited within the caisson around the piles and over the overlying soil to form the bottom for the concrete to be placed in the caisson; and,

(6) Concrete was placed in the caisson around the steel piles by means of a chute, the caisson proving to be water-tight, so that it was unnecessary to place an under-water concrete seal at the bottom.

---

[2] See, also, *Civil Engineering*, December, 1937, p. 843.

Prior to driving the piles, borings were made to determine the required lengths. A tolerance of 6 in. in the location of the center of the caisson caps was permitted, and no caisson moved more than this distance from its correct position.

In the process of construction, it was necessary to cut holes in the roof and second floor of the pier shed in order to place the piles and the steel cylinders in position. In driving, the tops of the piles were protected, somewhat ineffectually, by various types of cushions. Some of the rivets in the splices were loosened during driving. However, the ends of the abutting sections at the splices were faced and enough rivets used to insure that the abutting piles would be held in line. Fig. 3 shows the splices used. Each pile was designed for 100 tons and, as seen in Fig. 3, thirty-six shop rivets were used above the splice and forty-four field rivets below it. In the worst case, 25% of the shop rivets and 32% of the field rivets were loosened in the lowermost splice during the first stage of the driving. Assuming that further loosening of the rivets in this splice would occur in the second (final) stage of the driving in proportion to those already loosened, twenty tight shop rivets and twenty tight field rivets would still be left. This number is more than ample to comply with the specifications of the American Railway Engineering Association for splicing bridge chords.

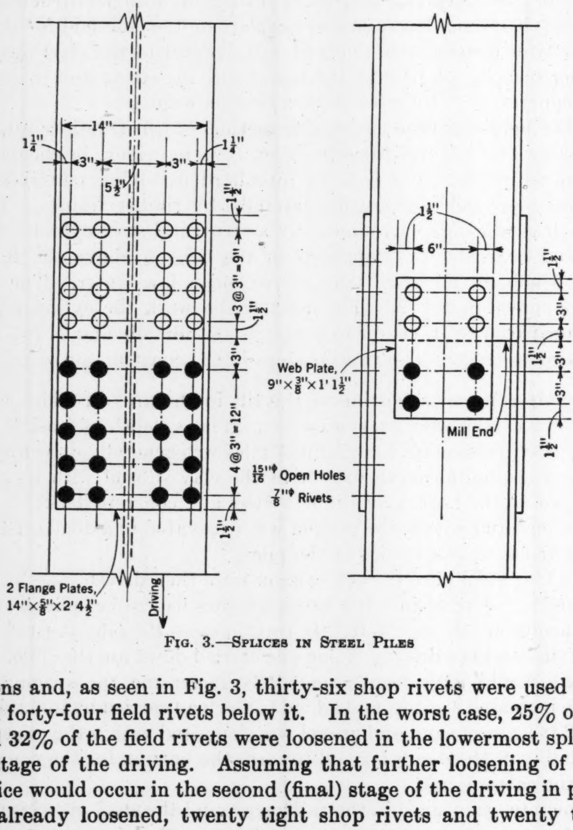

FIG. 3.—SPLICES IN STEEL PILES

After the cylinder piers were constructed, the platform shown in Fig. 4 was built. The wharf-shed columns were supported temporarily and the steel framework forming the support for the concrete deck was installed. The steel of this framework consisted chiefly of 30-in. and 36-in. H-beams of silicon steel placed longitudinally, and supporting transverse H-beams, also of silicon steel. The longitudinal members were usually continuous over two spans. Transverse expansion joints were provided at 80-ft intervals.

COMMONWEALTH PIER 5 BOSTON, MASS.

Fig. 4.—Arrangement of Steel Beams in Platform (Symmetrical About Center Line)

Head-House Foundations.—The method of reconstructing the wharf platform could not be used at the shoreward end of the pier under the head-house (which is a massive brick building extending out to within 20 ft of the face of the wharf platform), on account of the difficulty in supporting, temporarily, the heavy columns and brick walls of the head-house structure. Various methods were proposed for this part of the work and that finally adopted consisted of driving, to a limited depth, a light-weight steel sheet-pile bulkhead just outside the foundations of the building walls and filling the space between it and the existing sea-wall, to approximately low-water level, with a light-weight concrete. This concrete was placed in comparatively small quantities so that it would exert a minimum pressure against the steel bulkhead.

It was originally proposed to use fine and coarse coke aggregate for the concrete, and experiments were made to determine the feasibility of placing this class of concrete under water. These tests, on a small scale, were successful; but, when the coke concrete was deposited in large quantities through tremies, it was found that there was a tendency for the large pieces of coke to float. Therefore, cinders were substituted for the coke and the piles were protected up to low water back of the bulkhead by placing this concrete in place with a tremie. To protect the part of the piles above low water up to the bottom of the beam and column footings, forms were built around the pile clusters and on either side of the pile bents, using creosoted timber, and the spaces within these forms were filled with the cinder concrete. In this manner, it was possible to provide an efficient protection of all piles within the building site itself without the necessity of removing any of the structure. The adequacy of this method of protection was referred to William F. Clapp, Consulting Biologist, who reported as follows:

> "(1) Effect on Marine Borers Now Present. All destructive marine organisms require a constant flow of salt water containing a sufficient amount of oxygen to support life in the case of *Limnoria* and *Chelura*, and to supply food as well in the case of *Teredo*. The proposed protection would completely prevent the flow of salt water to the protected piles. This will result in the immediate extermination of all species of marine borers on or in the protected wood. There will be therefore no possibility of further pile deterioration from the marine borers now present. This has been demonstrated in numerous instances where protection of similar type has been used.
>
> "(2) Efficacy against Future Attack. Since the protection shown on the plans effectually prevents the free and continuous flow of salt water to the protected parts, under these conditions, no future invasion by marine borers of any type can take place. Consequently, in my opinion, the piles thus protected will be thoroughly safeguarded against future attack by any species of marine borer."

The platforms extending from the building outward to the face of the dock were removed, and new creosoted piles were driven to support a new concrete deck. The dock opposite the head-house had not been dredged to the full depth required alongside the pier structure itself, and when the platform piles were pulled in this part of the pier, it was found that the damage to them by marine borers had been less than farther out into the harbor where the water was materially deeper.

SUBSOIL INVESTIGATIONS

Preliminary investigations of the subsoil conditions were made by the usual wash-boring methods. Undisturbed samples of the clay were also obtained by a method developed under the supervision of Glennon Gilboy, Assoc. M. Am. Soc. C. E., in the Soil Mechanics Laboratory of the Massachusetts Institute of Technology, at Cambridge, Mass., in co-operation with the former Committee of the Society on Earths and Foundations. This process consists of driving a 6-in. casing into the soil, pumping and bailing out the water, and removing the soil by an auger to the elevation where the sample is to be secured.

A 2-in. pipe, enlarged to a 4-in. spoon, is then lowered through the casing into the soil and the sample cut off at the bottom of the spoon by a piano wire which extends to the top of the pipe. A vacuum is applied to the 2-in. pipe while raising, to help hold the sample in place. After it was finally decided to use steel piles driven to bed-rock, a series of core-borings was also made. The underlying bed-rock was found to consist of seamy slate rock varying, in elevation referred to mean low tide, from − 94.00 to − 142.67. Core-borings were also made to determine the elevation and character of the bed-rock.

PILE TEST

In view of the unusual length of the steel piles under consideration for the construction of the platforms and pier foundations, a test was made on one pile, consisting of a 14-in. by 14.5-in. by 89-lb steel bearing pile having a cross-section area of 26.19 sq in. and a total length of 137 ft and consisting of three sections which were spliced in the field during driving. The pile was driven through overlying materials, mostly blue clay, with a steam hammer, and to refusal on bed-rock. Refusal occurred 113 ft below mean low water, and ten blows were struck by the hammer without further penetration. At the conclusion of the test 54 ft of the pile was unsupported and 83 ft was in the blue clay. A steel loading platform and steel rails were used for the applied load, as shown in Fig. 5. The basic data applying to the test were as follows:

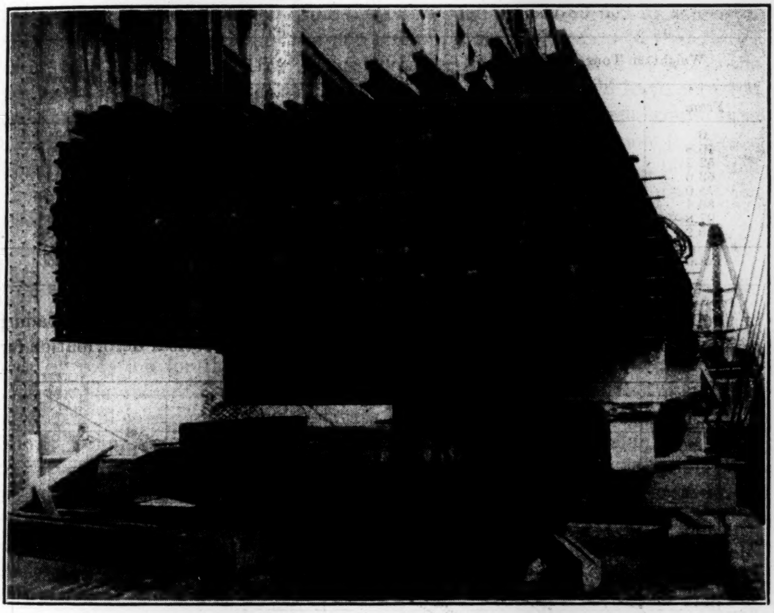

FIG. 5.—LOADING FOR TEST PILE

Description	Loads, in pounds
Weight of platform	10 552
Weight of cap	2 674
244 rails @ 880	214 720
Weight of hammer	14 000
Total weight (120.97 tons)	241 946

The deformation was measured at a point approximately 3 ft below the top of the pile and was observed from an initial load of approximately 40 tons to a maximum load of 121 tons at intervals of about 10 tons. The maximum load was allowed to remain on the pile for 24 hr, the total schedule being as follows:

Began loading April 14, 1936; loaded 63.6 tons; finished loading April 15, 1936, 11:30 A.M.; total load, 121 tons; began unloading April 16, 1936; 11:40 A.M.; and finished unloading April 16; 3:45 P.M. During unloading, observations were taken at intervals of about 10 tons from 86 tons until the pile was completely unloaded. The log of the pile-driving is given in Table 2 and a diagram of the deformation of the pile for various loads during loading and unloading is shown in Fig. 6 which also shows lines giving the theoretical deformation for lengths of 51 ft and 134 ft assuming the full load to be distributed over these respective lengths—that is, assuming no load to be transferred to the surrounding material.

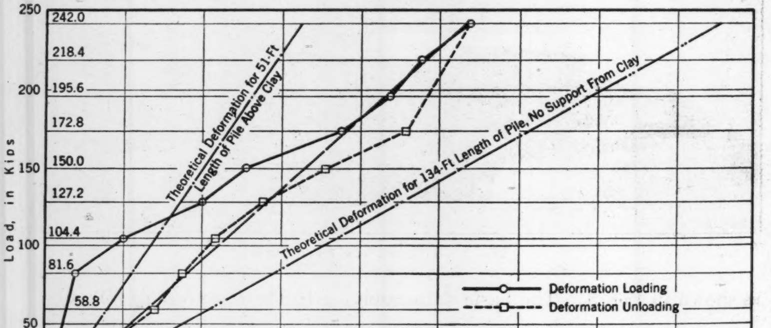

FIG. 6.—DEFORMATION DIAGRAM FOR TEST PILE

It will be noted that the deformation up to the load of 81 600 lb equals the permanent set of 0.002 ft as shown by the unloading diagram, this probably being equal to the penetration of the pile into bed-rock. From 81 600 lb to

195 600 lb, the deformation agrees very closely with that which would occur for the total length of 134 ft, which would seem to indicate that deformation was taking place over the full length of the pile. From a load of 195 600 to the full load of 242 000 lb, the deformation at all points was less than the theoretical deformation for a 134-ft length, indicating that during this period the load was being carried partly by the clay and partly on the rock.

When the pile was unloaded, the part above the clay first expanded at the theoretical rate for a 51-ft length of pile, the clay apparently holding the lower part of the pile firmly in position. From a load of 172 800 lb to a load of 127 200 lb the deformation of the pile was approximately equal to that for its entire length, namely, 134 ft. From the latter load to a load of 36 000 lb the pile expanded at a rate intermediate between that which would have occurred had the load been applied over its entire length and that which would have occurred had it been applied over only 51 ft of pile. It is impossible to discern from the diagram how much of the load was carried by the clay and how much directly on rock, but in the judgment of the writer, a considerable part of the load was carried by the clay.

Special Contract Requirements

Substitution of Steel Cylinders for Steel Piles.—After the contract for the work on the outer section of the pier had been signed and the work begun, the contractor requested permission to substitute steel cylinders driven into bed-rock by rotation for the steel piles included in the contract, and proposed a considerable reduction in the contract price if this change was approved. After careful consideration by the State Engineers, the Engineers of the Public Works Administration and the Consulting Engineers, permission was given for this change provided two test caissons could be driven successfully. Thereupon, the contractor undertook the construction of a test caisson. The experiment was not successful, however, as the material overlying the clay, consisting in part of rip-rap, offered such resistance that the trial cylinder was irrevocably damaged long before it reached bed-rock. Further efforts along this line were not made, and the construction was completed in the manner originally contemplated and described in this paper.

Removal of Existing Piles and Bracing.—The conditions of the contract required the eventual removal, in whole or in part, of all main piles, spur shores, and cross-bracing under the existing platform. Piles that interfered with the driving of steel piles or caissons were pulled, and other piles were cut off just above the ground surface. The existing fender piles and capping and the pile and timber corners were also removed and replaced by new fenders.

Avoidance of Interference with Business of Pier.—In order to avoid interruption of business at the pier as far as was reasonably possible, the pier was divided into five sections; the contractor was allotted one section at a time and was required to complete the work in that section before proceeding with work in another unless the pile and caisson work in another section could be done simultaneously without interfering with the business at the pier.

Settlement of Piles.—No settlement, either in the piles or in the concrete deck, has been discovered since the completion of the pier.

Bid Prices.—The following are some of the unit prices offered by the low bidder:

Caissons for the inner row, in place, per caisson	$ 790.00
Caissons for the outer row, in place, per caisson	1 050.00
Steel piles per pound	0.037
Structural steel per pound	0.050
Concrete per cubic yard	18.00
Yellow pine timber creosoted per 1 000 B. M.	120.00

Conclusions

The method of construction described in this paper, which involves the use of long steel piles driven to bed-rock and supporting a steel and concrete deck, is satisfactory for conditions such as existed at this pier. Furthermore, the use of a light-weight cinder concrete surrounding the wooden piles is a satisfactory method of protecting such piles from further damage by marine borers.

Acknowledgments

The thanks of the writer are due to the Hon. William F. Callahan, Commissioner, Richard K. Hale, M. Am. Soc. C. E., Associate Commissioner, G. H. Delano, Chief Engineer, John W. Ferguson, M. Am. Soc. C. E., District Engineer in Charge of the Boston District, and Charles J. O'Donnell, Assistant Civil Engineer, Massachusetts Department of Public Works. These officials co-operated generously in furnishing information and giving other assistance in the preparation of the paper. John Ayer, M. Am. Soc. C. E., with Mr. O'Donnell, assisted in writing it. Fig. 1 was supplied by the United States Engineer Department (Boston, Mass., District); Glennon Gilboy, Assoc. M. Am. Soc. C. E., made the tests on undisturbed soil samples in the Soil Mechanics Laboratory of the Massachusetts Institute of Technology, and, the description of the single pile test presented herein was written by B. A. Rich, M. Am. Soc. C. E.

DISCUSSION

WILLIAM G. ATWOOD,[3] M. AM. SOC. C. E. (by letter).—One possible method of reconstruction, used in some other piers in Boston, Mass., is not mentioned by Professor Spofford, and it would be interesting to know whether it was considered. Reference is made to the use of treated timber piles to replace the damaged piles. This would have made it necessary to remove the rip-rap but that might not have been costly enough to make this method uneconomical as compared to that used. By the use of timber-pile replacements the entire reconstruction of the deck might have been avoided.

The successful driving of piles of such great length is a tribute to the care and preparation by the engineers and contractors.

It may seem strange that the original designers of the pier did not protect the piles against the attack of marine borers, but the reason is clear to those who know the conditions in Boston Harbor. The investigation of 1922–1923 did not disclose the presence of borers in sufficient numbers to indicate that there was any danger from them. There were piers in the harbor that dated back to Colonial days, and there was no indication that they had ever been attacked; and there was no record of serious damage to any structures. Except for some of the railroad piers there was practically no treated timber in the harbor. The conditions in New York (N. Y.) Harbor are practically the same to-day, except that there is a history of attack by borers in the past.

The cause or causes of the invasion of borers into Boston Harbor is not known since there seems to have been little change in the water conditions. The cause of the heavy attack in the Harbor of Lynn, Mass., on the other hand, followed the removal of the sewage from the harbor and the consequent return of the normal oxygen content to the water.

There seems to be little doubt but that the protection of the substructures from attack by marine borers is cheap insurance. The cost of reconstructing two wharves in Boston Harbor, one of which[2] is described in this paper, would probably pay for the protection of at least 150 000 piles of normal length. Many other wharves have been rebuilt as a result of this attack and most of the remainder will have to be rebuilt eventually.

JOHN N. FERGUSON,[4] M. AM. SOC. C. E. (by letter).—The reconstruction of the platforms at Commonwealth Pier No. 5, Boston Harbor, was due to the action of marine borers on wooden pile foundations which made it necessary for a more permanent type of foundation to be provided. The unique and unusual features of the type of construction adopted are ably and concisely described in the paper by Professor Spofford. However, there are a few other items which may be of interest.

In addition to the creosoted piles used in the new foundations for the platforms at the head-house, creosoted timber piles and timbers for bracing were used for fenders along the outside edge of all platforms, and as fender clumps at the corners of the pier.

---

[3] Cons. Engr., Ithaca, N. Y.

[4] Dist. Waterways Engr., State Dept. of Public Works, Boston, Mass.

The specifications for creosoting read, in part, as follows:

> "All new piles driven in the fender system and platforms shall be southern yellow pine * * * . The piles shall be treated by the full cell process with 16 lb per cu ft of Grade 1 Creosote Oil. All timber below high-water line shall be treated by the full cell process with 12 lb of Grade 1 Creosote Oil * * * . The fender caps and the top planking of the corners may be treated with preservative salts if the Contractor so desires * * * ."

The fender system along the edge of the platforms consists of two plumb piles and a spur pile in sets spaced 10 ft on centers. The plumb piles are placed one behind the other, and the spur pile is bolted to the inner plumb pile just below a wale which is about 5.5 ft above low water. The top of the inner plumb pile is fitted with girder caps which are bolted to the platforms at intervals. The outer plumb pile is bolted to the inner plumb pile through a continuous longitudinal wale which extends between the plumb piles about 2 ft above low water. By this arrangement full flexibility of the upper 16 ft of the outer plumb pile is utilized.

The structural frame for the platform on the piles abreast of the head-house consists of reinforced concrete girders and beams instead of the silicon steel frame work that was used abreast of the freight sheds. To fasten the girders and beams to the piles, an inverted U-bolt was placed in the head of each timber pile.

The placing of the additional load of light-weight concrete on the pile clumps supporting the columns of the head-house has presented no apparent settlement, as might be evidenced by cracks in the plastering and artificial stone of the face of the building.

To protect the platform slab, a part of which was placed during cold weather, the contractor provided some trackmen's railroad hand-cars on which was built a frame of wood extending over two bays of the platform. This frame was covered with canvas, and heat to prevent freezing was supplied from the boilers of the contractors' floating equipment. As the work progressed the weather protection was moved along to a new section on the standard-gage track which extended the full length of the side platforms.

The concrete used in the platforms was all transit mix of the following proportion by volume: 1 part cement, 2 parts sand, 3.5 parts coarse aggregate, and 5.75 gallons of water.

JOHN AYER,[5] M. AM. SOC. C. E. (by letter).—In gathering data for this paper, copies of the specifications for the original construction of Commonwealth Pier No. 5 were found, and certain parts of them were of interest in determining the method to use in this work.

The piles and timber for the foundations of the retaining wall were of spruce. The piles for the wharf area outside the solid filled part of the pier were oak and were purchased under the following specifications:

---

[5] Cons. Engr. (Fay, Spofford & Thorndike), Boston, Mass.

> "All piles are to be new white or red oak sticks, with the bark on, sound, straight, and free from large knots or other imperfections which would materially affect the strength of the timber; not less than 50% of the piles to be white oak. They are to be not less than 14 in. in diameter 5 ft from the butt, and not less than 7 in. in diameter at point, when ready for driving, including the bark in both cases.
>
> "All piles from south of the fortieth degree of North latitude must be cut between the first day of September and the first day of March of the following year. North of that line they may be cut one month later.
>
> "When the heads of the piles have been prepared to receive the caps and before the caps are put on, they are to be thoroughly covered with a coat of the dead oil of coal tar, containing not less than 40% of naphthaline, applied at a temperature of not less than 120° F, or with such similar preparation as may be approved by the Engineer."

A similar specification as to the cutting of oak piles had been followed by the writer's firm until about 1930, when the question arose as to why piles should be so specified and whether winter-cut piles were not as susceptible to decay as summer-cut piles. Various persons were asked as to their opinion on this matter, and it seemed to be the general idea that summer-cut piles contained more sap and for this reason were more susceptible to decay.

To obtain a definite answer, the U. S. Forest Products Laboratory was asked this question, and replied in the form of its Technical Note No. F-15, which states as follows:

> "As a matter of fact, the time of cutting has very little effect upon the durability or other properties if the timber is properly cared for after it is cut * * *.
>
> "Timber, cut in late fall and winter, seasons more slowly and with less checking than during the warmer months. When proper storage or handling is impracticable, winter cutting is best. Fungi and insects do not attack wood out of doors in cold weather, and by the time warm weather arrives the wood is partly seasoned and somewhat less susceptible to attack. It is for this reason that winter cutting is advantageous and not on account of a smaller amount of moisture or sap in the wood in winter as the popular belief has it. There is practically no difference in moisture content of green wood in winter and summer."

This opinion is borne out by the Forest Products Laboratory of Canada[6] whose engineers also discussed the question as to whether winter cutting was more desirable than summer cutting, owing to difference in chemical composition.

Certain experiments conducted in Switzerland[7] on spruce and fir showed that "the wood is most susceptible to attack by fungi if felled during the period of greatest interchange of material in the tree." Furthermore, one year's seasoning under cover tends to obliterate differences shown by wood felled at different seasons.

It is generally recognized that if wood is cut in the spring or early summer and allowed to stay in the woods, or if it is not properly stored, it is extremely susceptible to attack by fungi; but if cut in the winter it has a chance to season somewhat and is less easily attacked by fungi.

---

[6] "Canadian Woods—Their Properties and Uses," published by Forest Products Laboratory of Canada, 1935, p. 190.

[7] *Loc. cit.*, p. 191.

The report of the Forest Products Laboratory of Canada states[7] further that:

> "The unfavorable environmental conditions to which summer-cut wood is exposed can, however, be overcome by proper handling of the felled trees, since they do not affect the inherent durability of the wood at the time of cutting."

Oak piles are always cut on order and shipped as cut. If oak piles are scheduled to be used during summer months, the piles will be cut and shipped as required on the work. They are not left exposed to attack by fungi. This question of winter-cut *versus* summer-cut piles was discussed in one report made by a certain engineer concerning a pier built some years previously. In this report it was stated that the oak fender piles which were then showing decay were not winter-cut as specified, and therefore such rot was to be expected in these summer-cut piles. It is probable that the specifications for this pier were written, in part, with the scissors instead of a pen, and that the time-honored specification for winter-cut piles was included without full knowledge as to why the piles should be so cut.

Provided that oak piles are cared for properly between the time they are cut and the time they are used, the time of cutting makes no difference in the durability of the piles so far as decay is concerned.

In the light of present knowledge, however, the provision in the specifications that the oak piles at Commonwealth Pier No. 5 be winter cut was well taken, not from the standpoint of resistance to decay, but rather from the standpoint of the bark remaining on them, thereby resisting the attack of *Limnoria* materially better than would peeled piles. As Mr. William F. Clapp has shown,[8] oak piles removed from Pier No. 5 on which the bark remained had been attacked but little by *Limnoria* and then only through the knot-holes or where the bark had been knocked off. The bark remains on winter-cut piles much longer than on piles cut during late spring or early summer. Observations at various points along the New England coast agree with those of Mr. Clapp that oak piles, where the bark remains, show little attack from *Limnoria*.

The fender piles for the reconstruction of Commonwealth Pier No. 5 are of creosoted yellow pine. Since about 1920 it has been extremely difficult to obtain long oak piles with tips of a proper size, and the butts of oak piles, where used for fender piles, showed signs of decay within a comparatively few years after installation. For this reason, it was decided to use creosoted yellow pine fenders and at the same time to provide floating fenders. This procedure has been followed in the reconstruction of another wharf in Boston Harbor during 1937. Creosoted yellow pine fender piles will show some wear from the floating fenders rubbing against them, but the creosoted pine fender piles, even under these conditions, will outlast the oak fender piles that it has been possible to obtain within recent years.

---

[8] "Recent Increases in Marine-Borer Activity," by William F. Clapp; paper delivered on October 7, 1937, before the Waterways Division of the Society at its Fall Meeting in Boston, Mass. (Abstracted in *Civil Engineering*, December, 1937, p. 836.)

CHARLES M. SPOFFORD,[9] **M. AM. SOC. C. E.**—Mr. Atwood has raised the question of why treated timber piles were not used in the reconstruction of this pier instead of steel piles. In reply the writer wishes to state that, before deciding to use steel piles, careful estimates of cost were made for a scheme involving the use of treated timber bearing piles, but the steel-pile scheme actually adopted was found to cost about the same and was believed to be much more permanent.

The discussion by Mr. Ferguson includes additional information relative to certain features of the reconstruction not touched upon by the writer, and that by Mr. Ayer should be of interest and value to engineers preparing specifications for timber to be used in salt water.

ENERGY MASS DIAGRAMS FOR POWER STUDIES

BY JOHN W. HACKNEY,[1] JUN. AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. EDGAR E. FOSTER, LYLE A. WHITSIT, AND JOHN W. HACKNEY.

SYNOPSIS

A method of applying the mass-diagram principle to complex hydro-electric power generation systems is developed and illustrated in this paper. This application involves the computation of potential energy inflow to the system, the segregation of energy lost due to friction, leakage, lack of capacity, evaporation, etc., and the study of the storage, waste, and use of the remainder by the mass-diagram method. That part of the energy which is storable is segregated by using two diagrams concurrently, one of total energy, the other of unstorable energy only, this device being necessary to insure against considering power developed at run-of-river stations to be storable.

GENERAL PROBLEM

The mass diagram as a "tool" for engineering analysis is familiar to the profession. In hydro-electric work it has been commonly used to compute the effect of storage on stream flow, and when used in this manner is simply the integral of the stream-flow record, or hydrograph, with respect to time. The outflow in terms of cubic feet per second, as determined from the study of this integral curve, is converted into kilowatts of power output by the use of a power-outflow diagram or a mean power constant. (This mention of the standard mass-diagram method is necessarily abbreviated. A complete discussion is presented elsewhere.[2]) This method of procedure is applicable to a single plant or to a storage plant above one or more run-of-river plants. If other storage plants are added, more complex systems develop. Hydro plants with little or no storage capacity are tied to high-head storage plants and the systems thus formed are tied into other systems on other water-sheds, so that a system may have plants of various storage characteristics, heads, and capacities using the water of several different streams.

NOTE.—Published in October, 1938, *Proceedings*.

[1] Asst. Hydr. Engr., Aluminum Co. of America, Pittsburgh, Pa.

[2] "Hydro-Electric Handbook," by William P. Creager and Joel D. Justin, Members, Am. Soc. C. E., p. 99.

It is desirable, if possible, to combine the power characteristics of such a system into a single diagram. This diagram should be adaptable to studies of power output under various load and water conditions, and to studies of various alterations or additions to the system. Such a diagram may be obtained by reducing the various stream-flow mass diagrams of the separate plants by the common denominator, power, to what has been termed an energy mass diagram.[3]

BASIC THEORY

The energy mass diagram measures the cumulative inflow of usable energy to the system with respect to time. When a cubic foot of water has entered a pond or a reservoir, it has a potential energy equivalent to its own weight falling from the height at which it entered the reservoir through the developed head of all plants through which it may subsequently pass. This potential energy may be stored, wasted due to lack of load or capacity, lost in friction, leakage, and evaporation, or converted into useful work. If the mean energy losses are segregated from the initial potential energy, and the remainder is plotted as an energy mass diagram, this diagram may be applied to the study of the storage, waste, and use of the available energy.

An energy mass diagram is the cumulative sum of the energy inflow (corrected for losses) to the hydro-electric system. It has the ordinary properties of a mass diagram. Being the integral of energy inflow, its slope is the rate of inflow and its ordinates are quantities of energy, or storage. In the usual hydro system, it is made up of two kinds of energy—storable and unstorable. Flow from uncontrolled parts of the water-shed represents unstorable energy and must be used as it comes. Flow from areas up stream from reservoirs may be stored to the extent that reservoir space is available. These classes of energy may be segregated by plotting not one but, two, energy mass diagrams. The first is the complete mass diagram, the cumulative sum of all energy inflow to the system. The second, an auxiliary curve, is the cumulative sum of the unstorable energy only.

The application of this basic theory is best explained by an illustrative example. The system chosen for the purpose is a simple one, consisting of one run-of-river plant and one head-water storage plant. It is believed, however, that the discussion of this limited system will reveal the salient features of more complex studies.

Hydro-electric power studies may be divided into three parts, the determination of stream flow available, the determination of load requirements, and the correlation of stream flow to load. The energy mass diagram is designed to be an aid in the study of the last-mentioned phase; therefore, the first two phases are not emphasized in the illustrative problem. This problem has been designed to indicate some of the uses of the energy mass diagram, given the stream flow and the load requirements.

ILLUSTRATIVE PROBLEM

Fig. 1 shows the water-shed of "Typical River"[2] in plan and profile. This river has the flow characteristics of a large stream of the South. "Type Creek," one of its tributaries, drains a fairly high plateau region, and, therefore, has quite a different run-off. The average monthly flows, listed in Table 1, were computed from the actual stream-flow records of corresponding streams.

* Corrected for evaporation. † Summations are for the end of the month.
‡ Arbitrary initial value on January 1.

On the main stream, well below the outlet of Type Creek, is a fairly large run-of-river plant, Plant *R*, with adequate pondage, but no storage. Provision has been made here for the installation of additional units when and if they are required. Now, in the course of events, another company acquires a reservoir site on Type Creek and plans a storage project to be known as Plant *S*.

The fundamental data concerning the two plants are as follows:

Description	Plant *R*	Plant *S*
Drainage Area, in Square Miles:		
Controlled	1 000	1 000
Not controlled	9 000	0
Total	10 000	1 000
Gross head, in feet	145	620
Capacity, in thousands of kilowatts	280	190
Storage, in thousands of acre-feet (pondage only)		603

The general problem is to determine the total increase in useful power output that will be produced by operating the new storage plant in conjunction with Plant *R*.

Computation of Illustrative Energy Mass Diagram

In order to construct energy mass diagrams for the "Typical Valley" plants, it will first be necessary to estimate the losses that should be deducted from the initial quantity of potential energy. Considering the storage plant, *S* (Fig. 1), the following major losses should be taken into account: (*a*) Evaporation; (*b*) loss of head due to draw-down; (*c*) pipe-line losses; (*d*) turbine losses; and (*e*) electrical losses. These items are variable with reservoir elevation, output, and other factors too numerous to mention. It is necessary to assume values for these losses that either are constants or that will vary only with natural phenomena, such as stream flow and time of year, which are not affected by the operation of the system. For Plant *S* the following assumptions have been used:

(1) Evaporation from the reservoir is a fixed quantity for any given month of the year;

(2) Loss of head due to draw-down is a mean quantity equivalent to the head lost when four-tenths of the volume of the reservoir is drawn (in this case, 30 ft);

(3) Pipe-line losses have a mean value of 20 ft;

(4) Turbine efficiency is 90%; and,

(5) Generation efficiency is 95 per cent.

Considering the foregoing losses the power output at Plant *S* may be determined. Let P = electrical power output; e = conversion efficiency; H = mean net head; Q = stream flow (corrected for evaporation); and, k = the power constant of the plant. Then,

$$P = 0.0846\, H\, Q\, e = k\, Q \qquad (1)$$

By Equation (1), $P = 0.0846 \times (620 - 20 - 30)\, Q \times 90\% \times 95\% = 40\, Q$ kw; and $k = 40$ kw per cu ft per sec. Similar assumptions as to losses have been made for the run-of-river plant (*R*, Fig. 1): (1) Evaporation is a fixed quantity for any given month; (2) the mean loss of head due to draw-down is 1 ft; (3) the mean conduit loss is 1 ft; (4) turbine efficiency is 87%; and (5) generation efficiency is 95 per cent.

Therefore, by Equation (1): $P = 0.0846 \times (145 - 1 - 1)\,Q \times 87\% \times 95\% = 10\,Q$ kw; and $k = 10$ kw per cu ft per sec. This factor, k, applies only to normal conditions of stream flow. If the flow is such that the capacity of the turbines is reached, or the head is reduced by high tail-water, k is no longer valid. For these conditions a curve of stream flow *versus* power is developed in three steps:

(*A*) Construct a curve of head *vs* capacity from turbine and generator characteristic curves;

(*B*) Construct a curve of head *vs* total stream flow by using head-water and tail-water rating curves; and,

(*C*) Construct a curve of stream flow *vs* capacity, using the curves developed in Steps (*A*) and (*B*).

In Step (*B*), since capacity limits are being determined the total stream flow is used with the tail-water curve; but this is reduced by the approximate turbine discharge in determining the head-water elevation from the rating curve of the dam.

Using the aforementioned constants, the energy mass diagram is developed using a computation table similar to Table 1, in which Column (5) gives the available energy from the inflow to Plant *S* acting through Plants *R* and *S*; that is, Column (3) times the sum of k-values for the two plants ($40 + 10 = 50$). Column (6) shows the available energy from the uncontrolled inflow to Plant *R* (Column (4) times $k = 10$). The effects of capacity limitations have been approximated. Column (7) is the summation for the auxiliary diagram; that is, the cumulative summation of Column (6) less the sum of the means of Column (5) and Column (6); and Column (8) is the summation for the main diagram, or the cumulative summation of Column (5) and Column (6), less the sum of the means of these columns.

Columns (7) and (8), Table 1, require some further explanation. It is convenient to plot energy mass diagrams in terms of cumulative excess over the mean, or an even value close to the mean. This produces a mass curve which moves in a generally horizontal direction and makes it possible to enlarge the vertical scale greatly without throwing the curve off the paper. It also produces more definite points of tangency and a more readable curve. For this reason, in Columns (7) and (8) the mean monthly energy inflow for the entire period of record is subtracted from the energy inflow for each particular month before it is added to the cumulative sum. This device usually makes it necessary to assign an arbitrary initial value to the cumulation in order to avoid negative quantities. The auxiliary diagram is plotted to the same mean as the main diagram in order that one slope scale may be used for both. Since the auxiliary curve is normally used only in wet seasons, it may be broken conveniently in the dry season each year to keep it from running off the paper.

COMPUTATION OF OUTPUT OF ILLUSTRATIVE SYSTEM

With the energy mass diagrams computed, the next step in the solution of the problem is to determine, by means of these diagrams, the maximum useful output that would have been produced by the two plants if they had been operated in conjunction for the period of stream-flow record. This requires a thorough-going investigation to determine the most efficient method of correlating stream flow and load. A discussion of the various methods of reservoir control and system operation is beyond the scope of this paper There appear to be as many "criteria" of operation as there are men interested in their development and use, but one and all may be tested and tried in a manner similar to that used for the trial of Typical River Operation Criterion, as outlined subsequently herein.

It is assumed that the Typical Valley plants have two types of load available: (1) The public utility load of two fairly large towns; and (2) a large electro-chemical industrial load. Continuity of service is the prime requisite of the public utility load. This power must be available at all times, and especially in the dryest years every effort must be made to protect the prime output required for this portion of the load. On the other hand, the electro-chemical industry finds it possible to use power which, although normally continuous, is nevertheless interrupted at long intervals by periods of sub-normal stream flow. Demand for the product during these dry periods will be satisfied from stock piles accumulated during the wet periods.

With such loads available for the system, it is proposed that a two-rate plan of operation be used. The higher, or normal rate, will be carried continuously except during abnormally dry years. In these dry years the prime, or utility, load only will be carried. It will be necessary, then, to develop some form of criterion that will indicate the proper times to drop and resume the secondary load. The drops from the normal rate must be timed so that the prime rates may be guaranteed through any sub-normal flow period; but, on the other hand, both drops and resumptions must be made in such a manner that the greatest possible total value of output may be obtained.

TYPICAL RIVER OPERATION CRITERION

The following criterion, although not the most efficient available, was chosen for its simplicity:

(1) There shall be designated a "normal rate" and a "prime rate" of power production;

(2) Power in excess of the designated "normal rate" shall be produced only from water which it is impossible to store; and

(3) Stored water may be used in generating power at any rate which does not exceed the normal, except when estimates show that, with the available stored water and assumed continuance of the prevailing stream flow conditions, the normal rate cannot be continued: For three months after July 1; for three months after August 1; for three months after September 1; or for one month after the first of any month.

When estimates have shown such a condition to exist, no storable water shall be used to produce power in excess of the prime rate until, at the end of a 30-day period in which the average stream flow has been greater than that necessary to produce the normal power, the reservoirs of the system have been completely filled. Then, only, shall the normal rate of power production be resumed.

Fig. 2(*a*) is the energy mass diagram for the Typical River system plotted from Table 1 for 1913 and from similar computations not included herein for the years 1914–1917. (In an actual problem the entire period of record should be considered, together with any additional information available concerning minimum flows.) The upper or main curve is the total usable energy inflow to the system, plotted in terms of excess over the mean. The lower, auxiliary, curve in Fig. 2(*a*) is the summation of unstorable energy only. It is plotted in terms of excess over the same mean. To the right of the curves is a slope diagram which is for the purpose of determining the rates of energy inflow

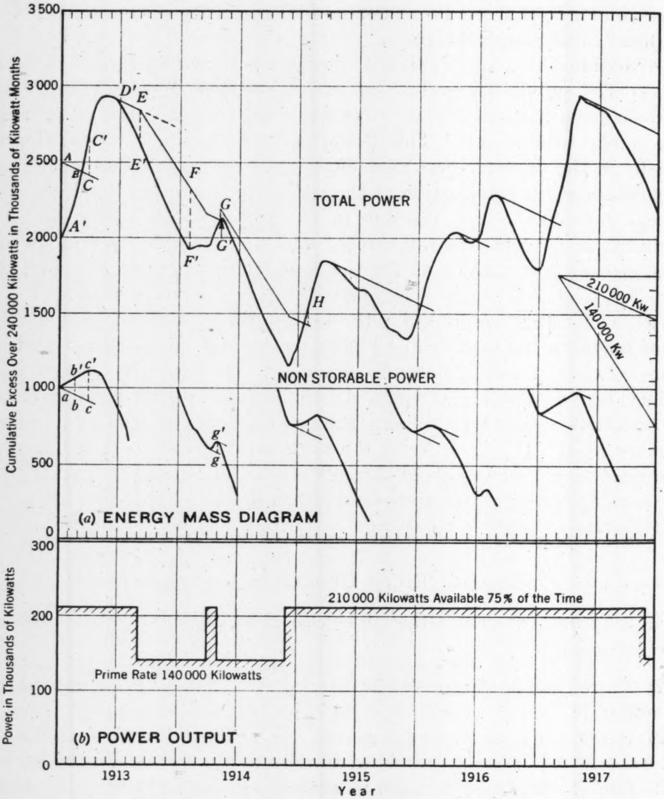

FIG. 2.—STORAGE VALUATION FOR "TYPICAL" RIVER PLANTS

and use corresponding to slopes of the mass curves. The vertical scale on the extreme left is used in plotting the curves and measuring storages.

The total amount of energy storage available at Plant *S* is determined by multiplying the storage volume of the reservoir in terms of month-second-feet by the sum of the *k*-values for the stations through which this storage will act. For Plant *S* this will be 603 000 acre-ft, or 10 000 month-sec-ft, times 50 = 500 000 kw-months of storage. With this storage, a determination of the output of the system will be made, applying the operation criterion, with a normal rate of 210 000 kw and a prime rate of 140 000 kw, to the mass diagrams of Fig. 2(*a*).

Assume that on January 1, 1913, the reservoir is at its point of maximum draw-down, and the system is operating at its normal rate. Ordinate *A A′*, Fig. 2(*a*), represents the reservoir depletion (500 000 kw-months), and the slope of Line *A C* represents the normal output rate (210 000 kw). Since the slope is less than that of the mass curve, inflow exceeds outflow and water is being stored at Plant *S*. If all the energy inflow to the system were storable, Point *B* would indicate the time at which the reservoir would be filled. However, if Line *a c*, which has a slope equivalent to the normal output, is drawn on the auxiliary diagram of unstorable energy, it will be found that the unstorable flow at Plant *R* is more than sufficient to provide the requisite 210 000 kw and some of this flow must be wasted. Ordinate *b b′* indicates that at this time the unstorable energy in excess of that used in carrying the normal rate has amounted to 170 000 kw-months since the first of the year; that is, 170 000 kw-months have been wasted or used as dump power, and, therefore, the reservoir is not filled by this amount. The reservoir will be filled only when the rate line, *A C*, has fallen below the mass curve a distance equal to the Ordinate *c c′* between the auxiliary curve and the rate line, *a c*.

From Point *C′* to Point *D′* Fig. 2(*a*), the energy inflow to the system still exceeds the normal outflow and since no more water can be stored a quantity of dump power is produced. The exact amount may be most easily determined from the tabulation of power inflows, making corrections for capacity limits at both plants. From Point *D′* to Point *E* outflow exceeds inflow and the normal rate is being produced by draft from storage, the storage depletion at any particular time being the ordinate between the rate line and the mass curve. At Point *E′* it will be found that, projecting Line *D′ E* and the slope at Point *E′* for three months, the ordinate at that point would exceed the storage available. This means that, if the present stream flow were to continue for three months, the normal output rate would exhaust the available storage. According to the criterion operation, this means that power production should be reduced immediately to the prime rate, represented by the slope, *E F*. Continuing on this new rate, the maximum storage used is *F F′* —about 420 000 kw-months.

The prime rate is used until April, 1914, when the run-of-river power at Plant *R* alone is sufficient to produce the normal rate. The question then arises at *g′* whether to continue at this rate or to drop again to the prime. On the auxiliary curve two tangents are drawn at a slope representing the normal rate. One is at the point where the slope of the auxiliary curve exceeds this rate, and the other where the normal rate exceeds that of the auxiliary curve. At Point G' on the mass curve the rate line has fallen below the curve, but subtracting the energy $(g\,g')$ produced at Plant R in excess of the normal rate by laying off this ordinate above Point G' it may be seen that the reservoir is not full and, therefore, stored water should not, according to the criterion, be used for the production of power in excess of the prime rate. Therefore, the normal rate is not resumed until the first part of December, when the run-of-river power is again sufficient to produce the normal rate. Stored water may again be used in the production of the normal rate after the reservoir is filled, at Point H, Fig. 2(*a*).

In like manner the remainder of the power graph (Fig. 2(*b*)) has been developed. To illustrate the methods used, only one determination of power output has been made. For a single actual problem the writer has made thirty-seven such determinations, using various criteria and different normal and prime rates. These results were analyzed graphically in order to select the best operating method. Assuming that this has been done for the Typical River plants, and that the criterion presented herein with a normal rate of 210 000 kw and a prime rate of 140 000 kw has been selected, it is possible to determine the increase in useful power output produced by operating storage Plant S in conjunction with Plant R.

Without the storage plant, but using available pondage at Plant R, the prime output is limited to the average output of the lowest week, which occurred in October, 1913, when the output was 23 000 kw. Duration curve studies indicate that a rate of 54 000 kw was available 75% of the time. Tabulating these data and the data from Fig. 2(*b*):

Description	Thousands of kilowatts of prime power available 100% of the time	Thousands of kilowatts of power available 75% of the time
With Plant S.........	140	210 − 140 = 70
Without Plant S......	23	54 − 23 = 29
Gain............	117	41

These data represent the power gain produced by building Plant S and operating it in conjunction with Plant R. Attention should be called to the fact that the actual gain is slightly greater, since the power available 75% of the time from Plant R alone is of poor quality, being interrupted at frequent intervals, as compared to the power available from the combined plants.

Conclusion

The illustrative problem has indicated a few of the uses of the energy mass diagram. It is not suggested as a cure-all for power studies. It is another "tool" to be used with analytical methods, the energy draw-down diagram, the hydrograph, the duration curve, and the area-duration curve. Each of these methods is useful in its own field, and the water power engineer should at least be familiar enough with all of them to select the one best suited to his own needs.

The chief advantage of the mass diagram is the great rapidity with which power determinations can be made, once the original computations have been completed. Every method of operation can be given a fair trial, and the engineer is encouraged to originate new methods by the ease with which they can be tested.

For a strict solution, every new plant or change in head would require a new diagram. This objection may be overcome by the use of proportion. The shape of the diagram is assumed to be typical of the water-shed, the addition of plants and changing of heads being represented by changes in scale. Used in this manner, the diagram becomes available for preliminary investigations, the determination of economic development limits, and other less refined calculations.

Limitations which must be borne in mind are the use of: (1) The graphical solution; (2) mean values for losses; and (3) weekly or monthly averages. Limitation (1) may introduce some errors due to paper shrinkage, inaccuracies in slope measurements, etc. However, the graphics may be checked analytically if necessary, using the summation columns for this purpose. Limitation (2) is a necessary feature of the method and may require special investigation of critical periods, such as the weeks of minimum stream flow. With judicious selection of these mean values, this feature will cause little trouble. The errors from Limitation (3) are common to all methods and have been thoroughly discussed elsewhere.[2]

In this presentation of the energy mass diagram no pretense is made of covering all the uses of the method. Ingenious minds will discover other devices and technical improvements which will alter it to fit their particular problems. The energy mass diagram has evolved from the ordinary mass diagram, and it may be hoped that even better methods of power computation will grow from the energy mass diagram method as herein set forth.

ACKNOWLEDGMENTS

The writer wishes to acknowledge his indebtedness to James P. Growdon, Robert F. Ewald, and Harold A. Thomas, Members Am. Soc. C. E., and also to the great number of other engineers whose ideas and methods have been consciously or unconsciously incorporated in this paper.

DISCUSSION

Edgar E. Foster,[4] Assoc. M. Am. Soc. C. E. (by letter).—The usefulness of the energy mass diagram for solving problems of power supply is well presented in this paper. As the author states, the idea of the energy mass diagram is derived by analogy from the mass flow diagram or curve; but, by substituting rates of energy or power for the stream flow the utility of the diagram is extended considerably. It may then be applied to any form of power generation, steam and pumped storage, as well as to hydro-electric power.

The basis of the extended utility may be easily inferred from a simple equation expressing the mass flow diagram, as follows:

$$B = \int_0^t Q\, dt \quad \text{.........................(2)}$$

in which B is the volume of water obtained at a given point in time, t, and Q is the rate of flow. For Q and B, similar quantities of other elements may be substituted. As the author has done in effect, E may be used for the total output of energy from a power system and e for the rate. Then,

$$E = \int_0^t e\, dt \quad \text{.........................(3)}$$

Integrating, $E = e\,t$, from which $e = \frac{E}{t}$, which is the average rate over the time, t. Expressing the equation in another form,

$$\frac{dE}{dt} = e \quad \text{.........................(4)}$$

that is, the tangent at any point equals the rate.

The writer used this type of diagram several years ago in a study to calculate the maximum prime power in a co-ordinated system of several reservoirs and run-of-river plants. Although the answer sought was only an approximation, the quantities and graph will serve very well to describe the process.

Thirteen proposed and existing plants were included in the system. There were five reservoirs with a total capacity of 75.4 billion cu ft of useful storage. On the assumption that the uppermost reservoir would be drawn down first and the procedure repeated for each successive reservoir down stream, and that the water was utilized at full head on the plants below, the energy equivalent of the storage was 0.843×10^9 kw-hr.

From previous study it was known that the critical period of the stream flow was that from January 1, 1930, to December 31, 1931. The problem, therefore, consisted in the determination of the maximum rate of prime power obtainable through that period with the given system of power plants.

---

[4] Assoc. Engr., U. S. Engr. Office, Denison, Tex.

The energy mass curve used in solving this problem is shown in Fig. 3 as Line $0\,A\,E$ for the period from January 1, 1930, to December 31, 1931. Following its construction, a part of the same curve was plotted parallel to itself at a distance of 0.843 billion kw-hr, as shown at Point E'. The entire curve was not plotted parallel because, as will readily be seen, only the critical parts need be repeated. A tangent, $A\ E'$, was then drawn from Point A on the main curve (at which point the reservoirs were assumed to be full) to Point E' on the upper segment. This completed the construction of curves.

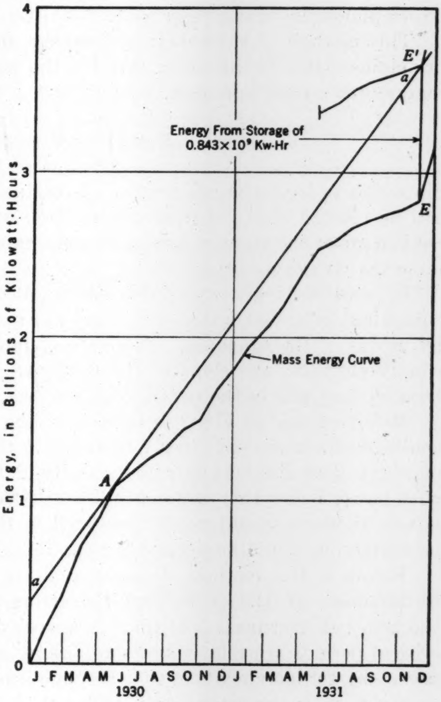

FIG. 3.—COMMON TANGENT ON PARALLEL MASS DIAGRAMS

The slope of this tangent, $A\ E'$, is the maximum prime power obtainable through that period of record. Point E' is the sum of the total power from natural run-off plus the regulated flow from storage. At Point E' all the reservoirs are empty and the maximum energy, therefore, has been obtained for the period. The time of E and E' is identical. Then,

$$E' = e'\,t \ldots\ldots\ldots (5)$$

in which e' is the rate of output from the time of Point A to the time of Point E', or,

$$e' = \frac{E'}{t} \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6)$$

which equals the maximum uniform rate of prime power. With Equation (6), e' is found from the slope of Tangent $A\ E'$. From Point a to Point a', the time is approximately 25.2 months, or 766 hr, and the total energy output is 3.6×10^9 kw-hr; or $e = \frac{3.6 \times 10^9}{766} = 197\,000$ kw, which is the maximum rate of prime power.

The author has constructed his energy mass diagram by using the differences between the monthly output of power and the mean for the period. The construction of the mass diagram from residuals does have an advantage (as the author has stated) in bringing into sharper prominence the critical points of a mass curve. The usual depressions caused by deficiencies of natural stream flow are filled in to some extent by the energy equivalent of storage, when a mass curve of energy is constructed from the output of a system of power plants, including reservoirs.

This method of construction, however, does not change the fundamental principles. If $\bar{e}$ is the mean rate for the period, the mass diagram may be represented by the equation,

$$E = \int_0^t e\,dt - \int_0^t \bar{e}\,dt \qquad (7)$$

Since this is true, the mass curve of residuals (or only the critical segments) can be plotted above the parallel to itself at a distance denoting the energy equivalent of the storage, and a common tangent can then be drawn to determine the maximum prime power.

By constructing two complete curves, at a distance representing the energy equivalent of stored water, the studies of operation can be readily conducted by means of the tangents. Any rate of power output can be introduced by simply changing the slope of the tangent. All that is necessary is that the tangent stay within the parallel mass curves.

Referring now to Fig. 2, it appears to the writer that the auxiliary diagram could be eliminated by simply limiting, in the calculations, the power output of Plant *R* to the normal rate—namely, 210 000 kw. By crediting Plant *R* with power below this rate instead of 280 000 kw as a maximum, the "dump" power or waste would not be included in the upper diagram and, therefore, no correction would be necessary as at Point *G*.

Errors of this method of power analysis are not serious enough to be objectionable. In the event that the errors arising from monthly means are too great, shorter periods of time, as a week or even a day, can be taken. The critical periods are relatively short and excessive work is not entailed by the use of shorter increments of time through such periods to refine the calculations as much as is consistent with the data. The errors of the process can be reduced by this means to limits within the errors of the original stream-flow and power-load data.

LYLE A. WHITSIT,[5] M. AM. SOC. C. E. (by letter).—That a mass curve of energy may be used to analyze a power supply in a manner similar to the use of a mass curve of flow to analyze a water supply, has been demonstrated in this paper. When the water supply is first determined by a mass curve, the result is then combined with the net head for power determination. If the power-generating system consists of a series of reservoirs and power houses on one stream and its tributaries, the use of water is in a concatenated sequence. The water availabilities at one plant depend upon the use of water from the reservoirs and in the plants up stream. The analysis by means of a mass curve of stream flow becomes complicated and cumbersome to the *n*th degree. As a result, the writer, like the author, proposed[6] the use of a mass curve of energy in 1913. However, even the use of the mass curve of energy is an unsatisfactory method.

[6] *Engineering News*, September 11, 1913, p. 496.

In the investigations and reports prepared since his earlier work, the writer has never found the use of the mass curve of energy advisable because of its complicated character and the precautions, adjustments, and corrections that are required. Graphs accompanying reports must necessarily be easily read, and their determination must be understandable to executives and other readers of a report. For this reason the writer believes that the use of duration curves of flow, or hydrographs, in combination with duration curves of load, are preferable.

Analysis by several duration curves or power graphs can be incorporated into one diagram. It is a method used in other analysis, such as the superposition of the hourly output of two or more generation stations, to produce a combined daily load curve of a power system. Such graphs can be made to show clearly the source of stored energy for later use, such as night storage for day-time or week-time peak-load use in the analysis of resources possessing pondage; or such as storage during high-water period for any rate of use during low-water periods.

At present (1939) there are very few power companies with generating systems made up entirely of hydro prime movers. Practically all have a complement of steam or other thermal generated capacity. In fact, it is very seldom that a hydro-electric project by itself can compete with a steam-electric project by itself. The proper position of hydro capacity, especially when it is equipped with storage regulation, is primarily one furnishing capacity, large amount of kilowatts for a small consumption of energy. Energy can be produced usually at much less cost by steam.

The economical arrangement results in the bulk of energy being produced from thermal plants because of lower cost; but hydro plants with pondage and storage can compete effectively in the production of capacity, that is, kilowatts of power in the peak of the load at a small energy consumption. Quite often an additional installation may be provided in such hydro plants to serve as the standby capacity for the system. When this portion of the installation is serving as standby for the other hydro capacity it is doing so at no extra consumption of energy, but when serving as standby for a base thermal capacity its energy use is at the detriment of the hydro peak carrying capacity. Perhaps the economical arrangement is to split the standby provision into hydro for the hydro load capacity and steam for the steam portion.

For this reason other forms of graph analysis, such as the duration curve or hydrograph, are more convenient and more commonly used in preliminary and final steps of the determination of a "load-carrying capacity" of a proposed project. In the determination of the load-carrying capacity, the plant output with unregulated water supply up stream from reservoirs is allocated to base load. The plant output of an unregulated water supply close to an up-stream storage plant is essentially a part of the storage plant and is allocated to peak load. The output of a plant with an unregulated water supply below a storage plant but with its own large tributary drainage area is probably allocated to base load.

JOHN W. HACKNEY,[7] JUN. AM. SOC. C. E. (by letter).—Mr. Foster suggests the use of two complete mass diagrams at a distance representing the energy equivalent of stored water. The writer believes that this is an excellent device for making the necessary operations more understandable, especially when the computer is inexperienced or when the computation must be explained to persons unfamiliar with the method. After using mass diagrams for a time and becoming familiar with them, this parallel curve will be found to be unnecessary.

Mr. Foster's suggestion that the auxiliary diagram may be eliminated by limiting the power output of Plant *R* to the normal rate is rarely practicable, since the normal rate is usually one of the unknowns of the problem.

Mr. Whitsit favors the "use of duration curves of flow, or hydrographs, in combination with duration curves of load," especially for graphs accompanying reports to executives and other non-technical readers. The writer agrees that mass curves are difficult to explain to such readers. However, duration curves are quite as difficult to explain and are often subject to misinterpretation. The best solution appears to be to solve the problem by duration curves, mass diagrams, or whatever other method is best suited, and then report the results, stripped of all non-essentials, in the manner most easily understood.

The writer also agrees with Mr. Whitsit that the energy mass diagram is not particularly well adapted to a study of the distribution of load between steam and hydro plants in a system operated at low load factor, or other problems of a similar nature. On the other hand, the energy mass diagram is well adapted to the solution of problems concerning storage in a system composed largely of hydro plants. As stated in the paper, the energy mass diagram is advanced, not as a method of solution for every problem, but as a method which the writer has found to be often useful and sometimes indispensable. To the person familiar with its use, the energy mass diagram is not complicated; on the contrary, it presents a picture of the inflow and outflow of power not easily grasped in a duration curve or hydrograph. As for the "precautions, adjustments and corrections" required, most of these are involved in the use of other methods and certainly all of them apply to the duration curve method.

The writer wishes to thank Mr. Foster for his explanation of the energy mass diagram from the viewpoint of the calculus involved.

MECHANICAL STRUCTURAL ANALYSIS BY THE MOMENT INDICATOR

BY ARTHUR C. RUGE,[1] ASSOC. M. AM. SOC. C. E.,
AND ERNST O. SCHMIDT,[2] ESQ.

WITH DISCUSSION BY MESSRS. JOHN B. WILBUR, WILLIAM J. ENEY, OTTO GOTTSCHALK, AND ARTHUR C. RUGE, AND ERNST O. SCHMIDT.

SYNOPSIS

A new method for the mechanical analysis of models of indeterminate structures is described. This method involves the use of a simple and inexpensive instrument known as the "moment indicator." A suitable technique for the application of the method to models made of semi-plastic materials like celluloid is described, and the results of measurements on a Vierendeel structure are given. Other applications are suggested.

The writers conclude that the technique discussed is capable of giving results accurate to 1%, and that an accuracy of 2% or 3% is easily obtained with considerable economy of time over other available methods of stress determination. It is suggested that the technique is suitable for use in practical engineering offices as a design tool.

INTRODUCTION

The purpose of the paper is to describe a simple and direct method of determining the bending moments in models of structural frames due to external loads. The method is particularly well adapted to the study of structures having a high degree of statical indeterminancy, whether the loading is static or dynamic in character.

For statical load conditions, the moment indicator is a simple and inexpensive instrument, capable of yielding very accurate results. The technique is of such simplicity and speed that it could well be adapted for routine design work in engineering offices. Less manipulative skill is required than for other available methods of mechanical analysis capable of giving comparable accuracy.

As to the merits of the model method for the analysis of complex structural problems, very little needs to be said beyond making reference to the excellent

paper by R. L. Templin, M. Am. Soc. C. E., published in 1937.[3] Several effective techniques have been developed for determining the stresses in structural models, the outstanding one being the deformeter method introduced by George E. Beggs, M. Am. Soc. C. E.[4]

No attempt is made herein to compare one model method with another, since each has its own particular applications for which it is especially suited. Indeed, the efficiency of any method is too closely associated with the skill and preferences of the investigator to make general comparisons possible. In so far as correctness of results is concerned, there is little choice between methods known to be based upon sound principles of mechanics.

After giving attention to the principle of the moment indicator, the writers confine themselves primarily to a description of its application to the particular case of celluloid models of two-dimensional indeterminate frameworks. The behavior of celluloid as a model material is discussed, and an adequate technique for dealing with it and with similar semi-plastic materials is described. Results of measurements and calculations for a four-panel Vierendeel structure are given in sufficient detail to establish the probable accuracy of the moment-indicator method. Other applications of the method are discussed briefly.

PRINCIPLE OF THE MOMENT INDICATOR

Consider a straight bar, subjected to bending moments and shear, and having no external loads, on a uniform section of length, L (see Fig. 1(a)). The moment indicator consists of a set of rigid levers attached at the ends of this section. The levers are provided with indices at one-third and two-thirds the length, L.

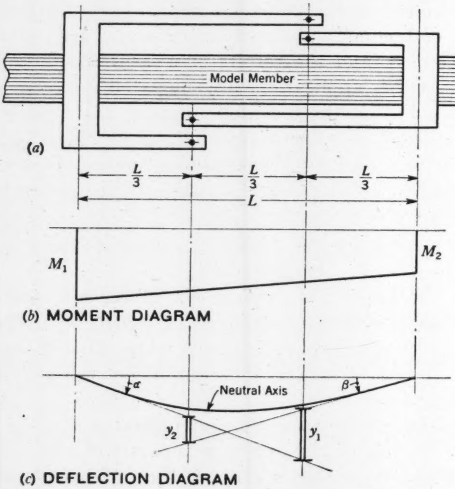

FIG. 1.—DIAGRAM ILLUSTRATING PRINCIPLE OF MOMENT INDICATOR

---

[3] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 1211.

[4] *Loc. cit.*, Vol. 88 (1925), p. 1208.

In Fig. 1(*c*), Deflections y_1 and y_2 represent the relative motions of the indices due to the applied bending moments of Fig. 1(*b*). The relation of y to M is easily found: $\alpha = \frac{M_1 L}{3 E I} + \frac{M_2 L}{6 E I}$, and $\beta = \frac{M_1 L}{6 E I} + \frac{M_2 L}{3 E I}$. Therefore:

$$y_1 = \frac{2}{3} L \alpha - \frac{1}{3} L \beta = \frac{M_1 L^2}{6 E I} \dots\dots\dots\dots (1)$$

The measurement of y_1 and y_2 thus gives the bending moments directly:

$$M_1 = \frac{6 E I}{L^2} y_1 \dots\dots\dots\dots (2a)$$

and,

$$M_2 = \frac{6 E I}{L^2} y_2 \dots\dots\dots\dots (2b)$$

At either point, motion of the indices toward each other corresponds to a positive bending moment. (In Fig. 1, M_1, M_2, α, β, y_1, and y_2, are shown positive.)

Equations (2) hold only if the shear deflections can be neglected. In short and deep bars the influence of shear must be taken into account, the correction to y being deduced as follows: The shear in the section equals,

$$s_s = \frac{M_1 - M_2}{L} \dots\dots\dots\dots (3)$$

The contribution of shear deflection to indicator reading is,

$$\Delta y_1 = - \Delta y_2 = \frac{s_s}{G A'} \dots\dots\dots\dots (4)$$

in which G is the shear modulus of the material, and A' is the effective area of cross-section in shear. Since Δy will be a small percentage of y (rarely more than 5%), it is sufficient to introduce the approximate values of M from Equations (2) into Equation (3); and to substitute for G, its value, $\frac{E}{2\left(1 + \frac{1}{m}\right)}$, in which m = Poisson's number. Then, Equation (4) gives:

$$\Delta y_1 = \frac{12 I}{L^2 A'} \left(1 + \frac{1}{m}\right) (y_1 - y_2) \dots\dots\dots\dots (5)$$

In the case of a bar of rectangular cross-section having a depth, d, $A' = \frac{A}{1.2}$ (approximately). Furthermore, for celluloid (and many other model materials), $\frac{1}{m} = 0.4$. There result, then, the corrections:

$$\Delta y_1 = 1.68 \left(\frac{d}{L}\right)^2 (y_1 - y_2) \dots\dots\dots\dots (6a)$$

and,

$$\Delta y_2 = 1.68 \left(\frac{d}{L}\right)^2 (y_2 - y_1) \ldots\ldots\ldots\ldots\ldots\ldots (6b)$$

Therefore, the true bending moments are:

$$M_1 = \frac{6\,E\,I}{L^2} (y_1 - \Delta y_1) \ldots\ldots\ldots\ldots\ldots\ldots (7a)$$

and,

$$M_2 = \frac{6\,E\,I}{L^2} (y_2 - \Delta y_2) \ldots\ldots\ldots\ldots\ldots\ldots (7b)$$

In many practical design problems, the correction represents an unnecessary refinement. It is so easily calculated, however, that it may as well be taken into account.

By obvious extension of the foregoing analysis, the effect of loads applied within Section L can be included. Curved bars and bars of non-uniform cross-section can likewise be treated by determining the appropriate slope-deflection coefficients, either experimentally or by calculation. In nearly all haunched-beam problems the moment indicator can be used on the straight uniform section between haunches. In certain special cases the indices may be placed profitably at points other than the third points, but the arrangement shown in Fig. 1 will be found most satisfactory for general use.

DESCRIPTION OF THE INSTRUMENT

In the practical design of the indicator, it is advantageous to deviate from the arrangement shown schematically in Fig. 1 to the extent of placing all the indicating levers on the same side of the bar. Fig. 2 illustrates a construction that was found very convenient and satisfactory for problems involving static loads. Except as shown, the parts are of aluminum.

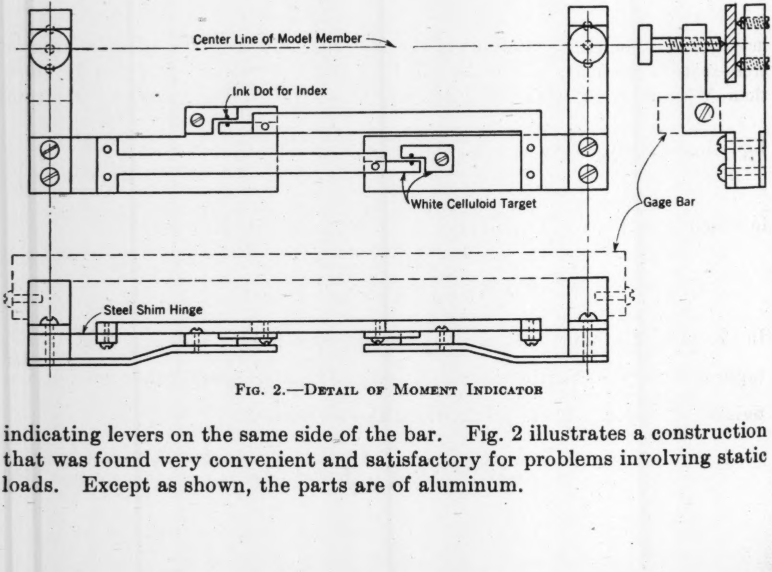

FIG. 2.—DETAIL OF MOMENT INDICATOR

The indicator is fixed on the model bar by two clamps (see Fig. 3), each provided with three sharply pointed screws. This clamping arrangement has the important advantage that no restraint is imposed upon the elastic deflections of the bar. The long levers are attached to the clamps by means of thin spring hinges, their free ends sliding on an extension of the short levers in order to keep the indices always in the same focal plane for microscope reading. It will be seen that the levers are placed so that the indices are approximately in the middle plane of the model bar; thus, twisting of the bar will not produce error in the reading.

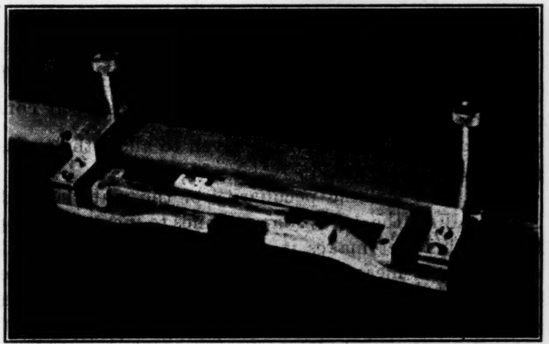

Fig. 3.—Moment Indicator Mounted on Bar: Gage Removed

The indices are small India ink dots on white celluloid. A gage bar, shown dotted in Fig. 2, conveniently sets the exact positions of the clamps and indices, the gage being removed after the clamp screws are tightened.

It will be evident to the reader that many interesting variations in design are possible. For example, one instrument was built with a gage length variable from 4 to 12 in. Furthermore, the sensitivity may be increased ten or more times by means of a magnifying lever, or by the use of measuring devices more sensitive than the ordinary measuring microscope. Extension of the principle to three-dimensional frameworks does not appear to be difficult, but has not yet been attempted.

Application to Celluloid Models

Celluloid is particularly well adapted to structural model work. It is isotropic and has a low modulus of elasticity which is sensibly constant up to fairly high stresses. It is very easy to work with either hand tools or machine tools, and it can be cemented perfectly with acetone, in which it dissolves.

Questions of similarity to prototype will not be discussed in this paper. It will only be observed that a celluloid model can be built to represent a given indeterminate structural framework with greater fidelity than a purely analytical treatment can represent it. Even when rectangular model sections are used to represent the members of a rigid frame structure, it is probable that the model will behave more nearly like the prototype than the hypothetical structure used as a basis of calculation.

Physical Properties of Celluloid

Samples of celluloid of different quality, age, and manufacture show marked differences in their mechanical properties. Moduli of elasticity ranging from

175 000 to 375 000 lb per sq in. will be encountered among commercial brands. Over the limits of any one sheet, however, the material is quite uniform. The following data may be considered as typical but cannot be applied quantitatively to any given celluloid. They were taken on samples of green celluloid, $\frac{3}{16}$ in. thick, known as "toothbrush stock."

For obtaining the data given herein, cantilever beams about 6 in. long and $\frac{3}{4}$ in. wide were used. The beams were tested at constant temperature in a water bath, ample time being given to allow the entire piece to come to temperature for each test.

The most striking peculiarity of the material is its creeping under load. After loading, the deflection continues to increase perceptibly for a considerable time. This fact makes it difficult to work with loaded celluloid models by conventional means. Fortunately, however, the creep-rate of celluloid is found to be independent of the magnitude of the load applied, within wide limits of stress. Stated in another way, the modulus of elasticity of celluloid is a function of time but is independent of stress up to the proportional limit. Were it not for this fact, semi-plastic materials like celluloid could not be used for accurate quantitative model studies by any known method.

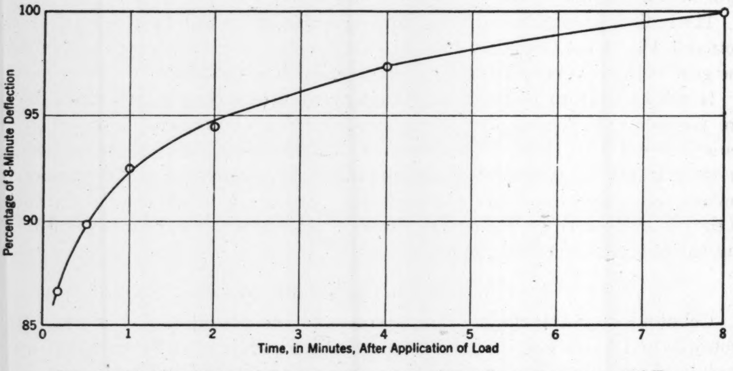

FIG. 4.—TYPICAL CREEP CURVE FOR CELLULOID (TEST TEMPERATURE, − 71° F)

A typical creep curve for stresses below the proportional limit is shown in Fig. 4. The data are plotted in terms of the percentage of the 8-min deflection reached at various times up to 8 min. Even after 8 min, the deflection had not reached a maximum. The curve was found to be the same for all stresses below the proportional limit, both for loading and for unloading. The proportional limit occurs at a stress of about 500 lb per sq in. for this material. At 1 000 lb per sq in., the secant modulus of elasticity is about 10% lower.

The modulus of elasticity is very sensitive to changes of temperature. Fig. 5 shows the behavior of the material under varying temperatures. The curve was taken for increasing temperature; after the material has been heated to somewhat more than 100° F, the curve cannot be reproduced. The sensitivity of the modulus at room temperature is nearly 1% per degree F. The coefficient of linear expansion was found to be 6.5×10^{-5} per degree F; that is, about ten times that of steel.

These data indicate the difficulties that have to be overcome in dealing with celluloid as a model material if results of high accuracy are to be obtained. Room temperature variations from day to day will often give considerable variation in modulus. In addition, temperature variations produce model movements due to direct expansion and contraction of the material. The effects of creep may be allowed for to some extent by timing readings by stop-watch, but this procedure is awkward and time-consuming. The effect of aging may sometimes be of importance.

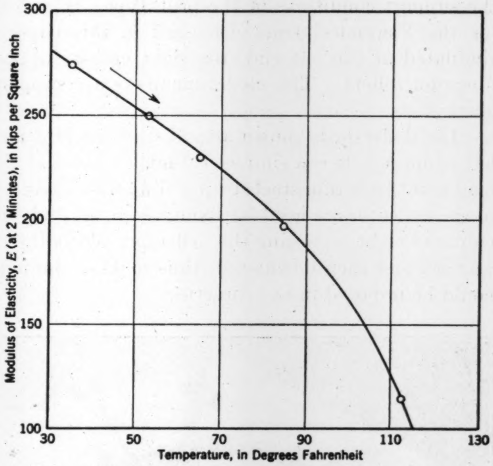

FIG. 5.—TYPICAL VARIATION OF *E* WITH TEMPERATURE

The technique developed by the writers for overcoming the aforementioned difficulties is described herein (see heading "Test Technique with the Moment Indicator"). It was found that by using ordinary loading methods and exceptional care in timing, the average accuracy obtainable was about 10%, due to temperature and creep effects. The technique described is capable of giving results accurate to within 1%, in addition to being more convenient and more economical of time.

TEST TECHNIQUE WITH THE MOMENT INDICATOR

Since the principal difficulties with celluloid as a model material have to do with its uncertain modulus of elasticity, the writers chose a test technique that does not depend upon the knowledge of that quality. The method used consists of imposing a constant deflection at the load point, instead of imposing a constant load. A celluloid model thus loaded is free from creep, since the load applied to it follows precisely the time variation of the modulus of elasticity.

The constant-deflection method, by avoiding difficulties with creep, makes the taking of readings on the indicator an easy matter. Of course, the indicator readings taken at various points on the structure give only the relative magnitudes of the moments. The absolute values are easily determined by the application of simple statics. Thus, it is not necessary to know the value of the modulus of the celluloid; nor is it necessary to know the magnitude of the deflection imposed upon the model, both quantities disappearing from the problem entirely.

The model to be studied is fixed upon the table in such a way as to simulate the support conditions of the prototype. Fig. 6 shows the arrangement used for the Vierendeel truss discussed in this paper. A fixed hinge support is simulated at the left end; the right end is supported by the equivalent of a hinge on rollers. The model members are supported on steel balls rolling on glass plates.

The deflector is shown attached at the first panel point to the right of the left support. It is a simple stiff lever hinged at the left end, connecting to the load point by a thin steel strap. Two nails driven into the table at the free end of the deflector are used for fixing the magnitude of the deflection imposed. A counterweight, opposing the deflector, allows the deflection to be imposed first upward and then downward, thus making the net deflection twice as large as could be imposed in one direction.

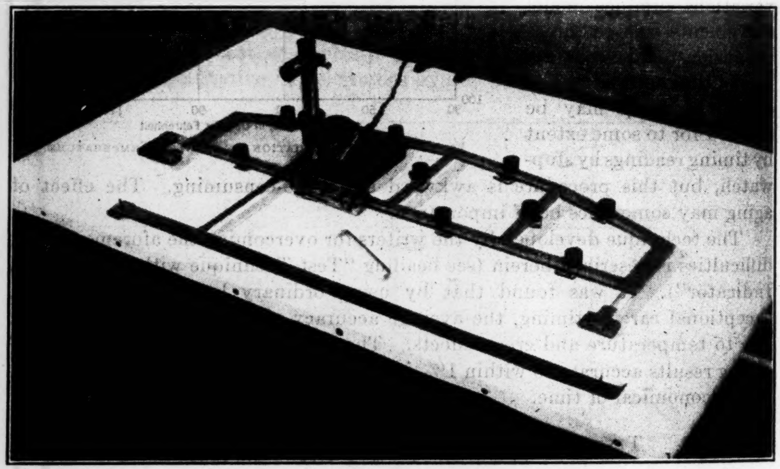

Fig. 6.—Vierendeel Truss Model with Deflector and Indicator in Position

In Fig. 6 the moment indicator is shown attached to a bottom chord member, and the microscope is in position for observing. The microscope is provided with a small spotlight which illuminates its field. This feature avoids the necessity of using a large lamp, the heat of which can cause annoying model movements.

It will be obvious that a number of indicator readings equal to the degree of statical indeterminancy, N, plus one is sufficient for the absolute stress determination throughout the structure. In the studies described in this paper readings were taken on all members of the structure on which it was possible to mount the indicator; that is, all except the end verticals, which were too short to accommodate the instrument being used. The extra readings were taken for the purpose of investigating the fidelity of the method.

The procedure is as follows: With the indicator fixed on any member, microscope readings of the relative index movements are made at both indices. Thus, the relative bending moments at the two ends of the gage length are determined from one instrument setting. From these two moments the moment distribution over the entire member is known at once. It was found very convenient to plot the readings (after being reduced by Equations (7)), directly on a line diagram of the truss, positive and negative moments being plotted above and below the line. The moment diagram is then constructed by drawing straight lines through the plotted points. The only unknown, *E*, is eliminated by applying simple statics to a section cut anywhere through the structure.

In order to secure the maximum accuracy, many more measurements were taken than would have been made in practice. Five successive measurements of the distance between index points were taken, with deflection applied alternately upward and downward. The indicator was read in two positions on each bar, with the levers first on one side and then the other. Such refinements are of value only in the investigation of the method itself, or when it is desired to work to accuracies greater than 1 per cent.

STRESSES IN VIERENDEEL TRUSS, OBSERVED AND CALCULATED

The dimensions of the Vierendeel model discussed in this paper are given in Fig. 7, and the relative moments of inertia of the members are indicated. The model was made of $\frac{3}{16}$-in., green celluloid. Butt-joints (cemented by means of acetone) were used for connecting the members, which were milled to the proper depth, since it was desired to eliminate the small errors always present in hand work. (Incidentally, it was found that when two or more pieces of the same depth were to be made, the pieces could be milled faster than they could be finished by hand, and the accuracy, of course, was much greater.)

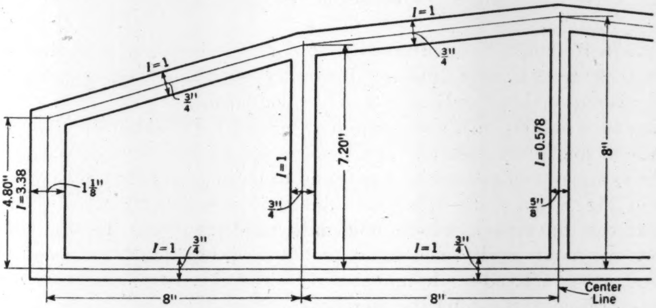

FIG. 7.—MODEL DIMENSIONS

In Figs. 8(*a*) and 8(*b*) all results are given in terms of the bending moments at the joints, in inch-pounds, due to a 1-lb load applied as indicated. The observed moments due, respectively, to a load at the center and at the side panel, are shown. The values in parentheses are the joint moments obtained by averaging all readings. The others are the joint moments as adjusted to make the summation of moments balance to zero at each joint. The joint closures are good, the maximum correction applied to produce balance at any joint being less than 1% of the largest moment in the structure.

FIG. 8.—OBSERVED AND BALANCED MOMENTS

Perhaps it should be mentioned that both the indicator and the deflector used in these tests were of home-made quality, such as can be achieved by any one who is reasonably handy with tools. Aside from the measuring microscope (reading to ± 0.0001 in.), the equipment needed for the indicator method can be made at negligible cost.

The symmetry of the model was found to be so good that only averages are given in Fig. 8, since the differences due to non-symmetry were of the same order as the differences between the individual readings. In a model made entirely by hand work, such symmetry would be highly unlikely, but for practical work, a hand-made model will be sufficiently accurate if reasonable care is exercised in finishing the members.

Upon comparing the results obtained by using only the first reading taken at any point with the result obtained by using the average of all readings taken there, it was found that the maximum difference amounted to 3.5%, with an average difference of less than 2 per cent. Thus, it may be concluded that one or, at most, two readings at each point will give sufficient accuracy for all practical work. The greatest errors due to using only the first readings are much less than the greatest errors in the theoretically calculated stresses, which are shown in Table 1.

The theoretical bending moments (see Columns (3), Table 1) were calculated with the usual assumptions for such structures. Member lengths were taken to be from center to center of joints. The effects of direct stress and shear were considered, but were found to have a negligible effect upon the results. The two sets of six simultaneous equations involved in the calculation were computed on the "simultaneous equation machine"[5] which eliminates most of the labor usually encountered in obtaining sufficiently accurate results.

* See Fig. 8.

The percentage differences between calculated and measured moments are designated as "error" (Columns (4), Table 1). On the basis of the demonstrated accuracy of the moment-indicator method, these values may properly be regarded as a good measure of the errors in the theoretical results for the structure studied. The truss discussed is fairly ideal from the standpoint of theoretical analysis; it was not the intention of the writers to select a structure showing large differences between actual and calculated stresses.

FURTHER CONSIDERATIONS

One marked advantage of the method described lies in the fact that the stresses are measured by a device wholly external to the structure. In dynamical models such an approach is almost indispensable.

By arranging the instrument for photographic recording of the relative index motions, the indicator (or "moment recorder" as it is then called) has been used for studying the bending stresses in a model of a building frame vibrating as a result of earthquake motions. In problems of this nature it is clearly not practical to determine the bending stresses from records of the deflections of the model, on account of the tremendous labor involved when the model has several degrees of freedom.

---

[5] "The Mechanical Solution of Simultaneous Equations," by John B. Wilbur, Assoc. M. Am. Soc. C. E., *Journal*, Franklin Inst., Vol. 222, No. 6, December, 1936.

Perhaps the most valuable application of the method may be to the study of the so-called secondary stresses in trusses. In certain types of trusses, it is well known that the conventional analytical secondary stress determination leads to serious errors, and a truly accurate analysis requires such a mass of work as to make its application practically impossible. With the sensitivity of the indicator increased several-fold, it should be ideal for measuring secondary stresses in models.

The indicator may also be found useful in certain full-sized tests. With two sticks clamped to a beam or girder, the bending moments acting could be measured accurately with less effort than by the customary strain-gage measurements. A gage length of several feet gives large deflections, the deflection increasing with the square of the gage length, as seen from Equations (2).

For routine model work, it would be desirable to have several moment indicators, in order to effect a further saving of time by avoiding moving the instrument from member to member.

In some instances, it may be desired to ascertain the absolute magnitude of the bending moment at a point in the model, without having to measure the $N + 1$ moments previously mentioned. This can be accomplished through the simple expedient of a "spring balance" made of the same material as the model, as shown diagrammatically in Fig. 9.

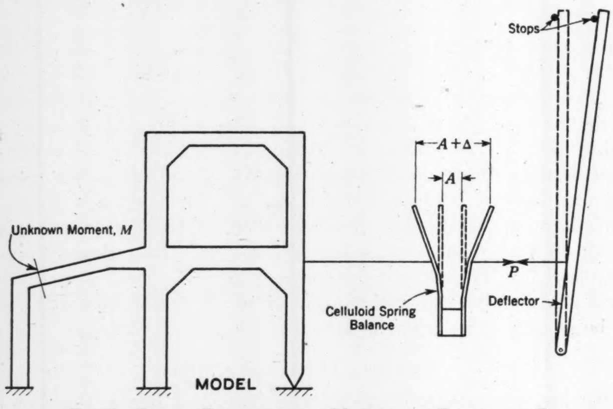

FIG. 9.—DIRECT ELIMINATION OF MODULUS OF ELASTICITY, E

The "spring balance" is made of two bars so supported as to be statically determinate. Any other calculable or calibratable system will serve the purpose equally well. The purpose of the balance is to weigh the load imposed upon the model in terms of the modulus of elasticity of the material.

Let P be the load applied due to the deflection imposed by the deflector, and let Δ be the resulting relative motion of the indices of the balance. Then, if the moment indicator reading for the unknown moment, M, is y, the following relations may be written:

$$M = K_1 E y \qquad (8a)$$

and,

$$P = K_2 E \Delta \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (8b)$$

in which K_1 and K_2 are known constants. Consequently,

$$M = \left(\frac{K_1}{K_2} \times \frac{y}{\Delta}\right) P \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (9)$$

Thus, the unknown, E, which is a function of time and temperature, is made to disappear directly.

CONCLUSIONS

The moment indicator offers a simple and inexpensive means of analyzing indeterminate structural models. The technique involved is so easy and straightforward that a minimum of skill is required. Results accurate to 2% or 3% are obtainable with an average time consumption of less than 2 min for each moment measured. By taking a few more measurements than are required, the method is made self-checking.

The writers believe that the method described in this paper is sufficiently practical to commend itself for use in engineering offices as a design tool. Any one who can read a measuring microscope can become proficient in the use of the device within an hour. The construction of celluloid models of most frames met in practice is a simple matter, requiring few tools and little skill. An office assistant under the guidance of an engineer could be entrusted with all the detail model work and observations.

DISCUSSION

JOHN B. WILBUR,[6] ASSOC. M. AM. SOC. C. E. (by letter).—By the development of the moment indicator, the authors have not only made an important contribution to the available instruments for model analysis, but have opened the way for further development along similar lines. In the past, many different types of strain-gages have been developed for the measurement of linear strains, but the measurement of angular strains has not received as much attention. The moment indicator measures angular strains in such a manner that bending moments are easily obtained.

After describing the application of the moment indicator to the determination of moments in a Vierendeel truss model, the authors discuss several possible future developments of the instrument (see heading, "Further Considerations"), stating that a "valuable application of the method may be to the study of the so-called secondary stresses in trusses." They declare also that " * * * in some instances, it may be desired to ascertain the absolute magnitude of the bending moment at a point in the model, without having to measure the $N+1$ moments previously mentioned," and suggest that "this can be accomplished through the simple expedient of a 'spring balance' made of the same material as the model."

Subsequent to the presentation of the paper, further research under the direction of the writer has led to an investigation of these suggested applications. Since this investigation was based directly on the tentative suggestions made in the paper, a synopsis of the results obtained should be of interest.

The primary purpose of the later investigations was to determine, by means of the moment indicator and celluloid models, secondary bending moments in trusses with rigid joints. Three basic problems were present: First, it was necessary to devise a method of attaching the moment indicator to model members so that its readings would not be influenced by shear distortions, because in truss models used for this purpose it is often necessary to use **I**-beams or their equivalent for members, the shear deflections of which are rather large, and impossible to determine accurately; second, it was necessary to magnify the readings of the moment indicator by a lever system, in order to insure sufficient precision of the microscope readings; and third, it was necessary to build and use a celluloid "spring balance," as illustrated in Fig. 9. Although the theory of the spring balance had been developed previously by Mr. Schmidt, it had not been tested by actual use. Equations of statics which are usually available for the conversion of relative values of moments (as measured by the moment indicator without the use of the spring balance) to actual values of moments due to the applied loads, are not present in dealing with the determination of secondary moments in trusses, so that it was essential that the spring balance be used.

---

[6] Associate Prof., Civ. Eng., Mass. Inst. Tech., Cambridge, Mass.

An investigation by Mr. Johann Meier[7] showed that, for a rectangular beam, a transverse section which is plane before bending will, if not adjacent to points where external loads are applied to the beam, deform due to shear so that it takes the shape of a cubic parabola. Mr. Meier not only reached this conclusion from analytical investigations, but obtained an excellent experimental check working with a celluloid model. Near points of applied loads, however, longitudinal linear strains are affected by shear distortions, and the resulting variation from linear distribution in stresses normal to transverse sections causes shear distributions that are no longer parabolic, and shear distortions of transverse sections that are no longer in the shape of a cubic parabola. Because of the effect of Poisson's ratio, transverse linear stresses due to applied forces also affect strains normal to transverse sections, and, in turn, shearing distortions. Because of the uncertainty as to the shape which transverse sections will take as a result of shear distortion under varying circumstances, it was concluded that corrections to moment indicators, to allow for shear distortion effect, could at best be only approximate if the arms of the indicator were each attached to two points on a transverse section. Under no circumstances can the shear corrections be computed and proper corrections applied, when the moment indicator is attached to a member within a distance from the member support equal to the width of the member. When shear distortion is small, the errors due to this source are likely to be negligible, but in model studies for secondary moments in trusses, this may not be the case. It was believed highly desirable, therefore, to devise a method of attaching the moment indicator arms to members so that readings would not be influenced by shear.

After an extended investigation, it was shown by a model study that this could be accomplished for a moment indicator of the same dimensions as that described by the authors, by attaching an arm of the moment indicator to a member at two points 0.25 in. apart, both lying in the neutral axis of the member. Attached in this manner, it was found that readings were not only uninfluenced by shear distortions, but that small errors due to other resulting sources were negligible. These negligible errors result from two causes: (1) The partial restriction of linear strains along the neutral axis between the two points of attachment; and (2) the fact that the arm of the indicator now is parallel to the chord joining the two points of connection to the elastic curve of the member, rather than tangent at a point half-way between these two points. The moment indicator designed for tests for secondary moments was built with this means of attachment, and it is believed that future indicators of this type should adopt this improvement. Simpler procedure as well as more accurate results may be obtained.

The rate of change of slope in members of a truss is not as large as it is in members of rigid frames without diagonals, so that a more sensitive moment indicator is required than would otherwise be the case. For this reason, a special moment indicator was built, which differed in two respects from that described in the paper. A lever system was inserted in the indicator which magnified the readings five times as compared to those which would otherwise have been obtained. Due to the presence of this lever system, it was desirable to omit the feature of the moment indicator which enables one to determine moments at both sections of attachment. In order to simplify the construction of the instrument, provision was made to determine moments at only one end of the indicator for a given setting on a member.

---

[7] "An Experimental Check of the Theory of Shear Deformation and Shear Deflection," by Johann H. Meier. Presented in partial fulfillment of the requirements for the degree of Master of Science, at Mass. Inst. Tech., Cambridge, Mass., 1938.

The practicability of the celluloid spring balance was first tested by measuring moments in a rigid frame without diagonals, using a celluloid spring balance in the line of loading. From a series of tests conducted in this manner, it was demonstrated that the idea could be used successfully, and that the accuracy of the moments thus obtained was comparable to that resulting from converting relative values of moments obtained without the spring balance, into actual values of moments, by the application of equations of statics. In the tests on celluloid trusses which followed, it was necessary to design the celluloid spring balances carefully, so as to make certain that they would be flexible enough to permit accurate readings, but at the same time strong enough so that they would not be over-stressed.

In a rigid frame without diagonals, where the loads are carried largely in bending, errors in model construction due to slight eccentricities in the members meeting at joints are not important, because the moments due to these eccentricities are small in comparison to the moments in the members meeting at the joint. Under these circumstances the moments in the ends of the members meeting at a given joint, as determined by the moment indicator, will be found to be nearly in static equilibrium. In trussed structures, however, eccentricity moments due to unavoidable, slight errors in model construction are relatively large in comparison with measured secondary moments. For this reason the moments measured at any joint may fail to be in static equilibrium by an appreciable amount. Therefore, a correction to the measured moments is necessary. This may be accomplished by distributing the unbalanced moments, as measured by the moment indicator, by the method of moment distribution, and combining the results of this analysis with the previously measured moments. An alternate procedure might be followed on the model by applying moments at different joints, successively, and measuring the resulting moments set up in the members of the model, thus obtaining data to be used as a basis for corrections due to the eccentricity of members.

In comparing secondary moments as determined by model studies with analytical values for corresponding moments, an excellent agreement was found, with the exception of isolated cases in which, due to improper model design, the secondary moments were so large that the celluloid of the model was apparently stressed beyond its elastic limit. At such points, measured moments were appreciably lower than computed values.

It is believed that model studies of secondary stresses with the moment indicator are thoroughly practical, and that they offer an excellent approach to further investigations in the field of secondary stresses.

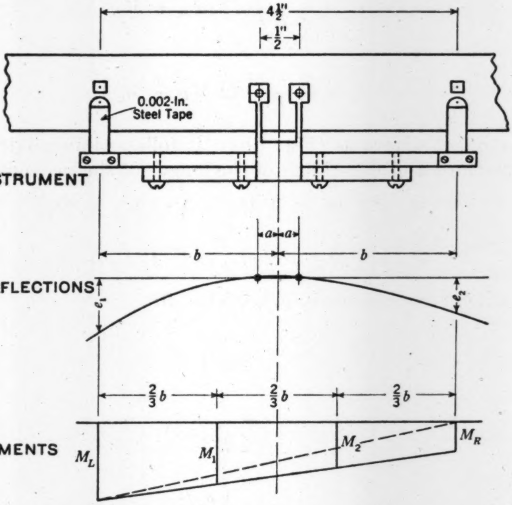

FIG. 10

It is of interest to consider types of moment indicators that differ in principle from that described in the paper. Perhaps the most direct method of determining bending moments in models is to measure the change of slope between two sections by means of two arms, normal to the member, each rigidly attached at points equidistant from the section where moment is to be determined. The measurement of the relative movements of points on the ends of the arms makes it possible to compute the bending moment by the moment-area theorem. This method was probably first devised by Professor Beggs, and has been used successfully under a variety of conditions. For use in celluloid models, however, it has been found that moment indicators, similar to that described by the authors, offer certain advantages, due mainly to simpler technique of application, and freedom from direct stress indication superimposed upon the moment indication.

Several other types of moment indicators which differ in principle from that of the paper were designed in the Structural Analysis Laboratory in 1937. One of these designs, which will be referred to as Type II, holds considerable promise, and was actually constructed and tested. The theory of this type of moment indicator may be explained by reference to Fig. 10. In Fig. 10(*a*), e_1 and e_2 are the deflections of the ends of the instrument, measured relative to the chord through the two points of attachment to the beam, which are near the center of the instrument.

Deflections e_1 and e_2, in terms of the moments at the ends of the instrument, can easily be calculated, using, for example, the method of virtual work. They are:

$$e_1 = \frac{b^2 - a^2}{6\,E\,I}(2\,M_L + M_R) \ldots\ldots\ldots\ldots (10a)$$

and,

$$e_2 = \frac{b^2 - a^2}{6\,E\,I}(2\,M_R + M_L) \ldots\ldots\ldots\ldots (10b)$$

From the moment diagrams (Fig. 10(*c*)) it follows immediately, for the moments at one-third and two-thirds of the length of the instrument, that:

$$M_1 = \tfrac{2}{3}\,M_L + \tfrac{1}{3}\,M_R = \tfrac{1}{3}\,(2\,M_L + M_R) \ldots\ldots\ldots\ldots (11a)$$

and,

$$M_2 = \tfrac{2}{3}\,M_R + \tfrac{1}{3}\,M_L = \tfrac{1}{3}\,(2\,M_R + M_L) \ldots\ldots\ldots\ldots (11b)$$

Introducing these expressions in Equations (10):

$$e_1 = \frac{b^2 - a^2}{2\,E\,I}\,M_1 \ldots\ldots\ldots\ldots (12a)$$

and,

$$e_2 = \frac{b^2 - a^2}{2\,E\,I}\,M_2 \ldots\ldots\ldots\ldots (12b)$$

from which,

$$M_1 = \frac{2\,E\,I}{b^2 - a^2}\,e_1 \ldots\ldots\ldots\ldots (13a)$$

and,

$$M_2 = \frac{2\,E\,I}{b^2 - a^2}\,e_2 \ldots\ldots\ldots\ldots (13b)$$

Therefore, readings at the ends of the instrument are proportional to the moments at the one-third point and at the two-thirds point of its length.

Type II has not been as thoroughly investigated as the instrument described by the authors, but it is believed that it will give about the same accuracy of results. Its readings are not affected by shear distortions, and the labor involved in using the instrument may be somewhat less. Clamping the instrument to the center of a member rather than nearer its ends may be advantageous because of the effect of uncertain stress distribution in members near joints.

Type II is not mentioned for the purpose of comparing it with the moment indicator in the paper, but rather to illustrate the wide variety of instruments of this type that may be devised, and in this manner to bear out the thought that Professor Ruge and Mr. Schmidt have opened the way for important developments.

WILLIAM J. ENEY,[8] ESQ. (by letter).—In developing the moment indicator, the authors have made a very worth while contribution to the art of model analysis. As with all fundamental things, it is simple; and, as stated by the authors, it has many possibilities.

---

[8] Asst. Prof., Civ. Eng., Lehigh Univ., Bethlehem, Pa.

A structure composed of members with constant cross-section was wisely selected to serve as a demonstration of the method. The authors show that if the moment indicator is attached to a member of variable section, the appropriate slope deflection coefficients must be determined, either experimentally or by computations, before the moments are known. Since a large number of structures include variable section or curved members, the writer wishes to demonstrate a simple experimental procedure for treating such cases.

For determining these coefficients, use may be made of the apparatus shown in Fig. 11. This was originally designed to serve both in the determination of the elastic constants for the Cross moment-distribution method and as a deformeter gage for mechanical stress analysis. It is more elaborate than necessary for the purpose at hand. A large-scale model is made of that part of the frame model on which the moment indicator readings are taken and is attached to the gages, which are adjustable along a fixed aligning bar. End moments are applied by measured longitudinal pulls on the gage arms until the rotations of the arms are of the proper value. The effect of shear is automatically taken into account so that the true moments are obtained. In detail, the logic and procedure are as follows: In Fig. 12(*a*), the moment indicator is shown attached to a member with variable cross-section. Due to external loads on the structure, acting outside the gage length, the member deflects and the relative motions of the indices at the third points, y_1 and y_2, Fig. 12(*d*), are measured. The rotations of the elastic tangents at Points *A* and *B* relative to the chord, *A B*, shown as Angles α and β on Fig. 12(*d*), are:

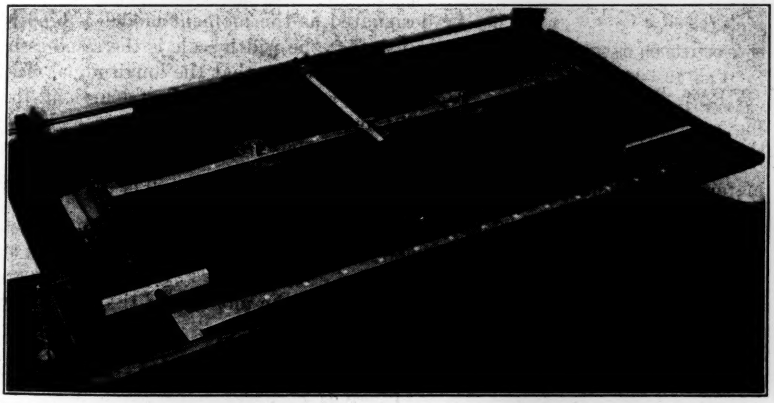

FIG. 11.—APPARATUS USED TO TEST MOMENT MODEL

$$\alpha = \frac{y_4}{L} = \frac{2\,y_1 + y_2}{L} \qquad (14a)$$

and,

$$\beta = \frac{y_3}{L} = \frac{2\,y_2 + y_1}{L} \quad \ldots\ldots\ldots\ldots\ldots\ldots (14b)$$

The distances, y_3 and y_4, are relatively small, compared with the gage length, L, and, therefore, the angle, in radians, and its tangent can be taken as equal.

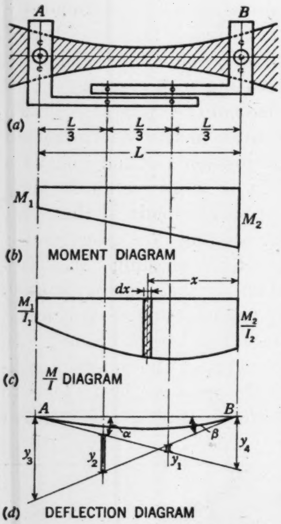

FIG. 12.—DIAGRAM ILLUSTRATING PRINCIPLE OF MOMENT INDICATOR.

The problem, then, is to determine what moments applied at Points A and B (Fig. 12(a)) of the frame model produce end rotations of α and β, respectively. It is not convenient to ascertain these values by applying moments to the frame model, nor to remove this section for testing and, later, to replace it by cementing with acetone. With such a small model, the application of the moments to produce the exact end rotations, α and β, would be tedious, and precision would be difficult to obtain. However, if this section of the frame model is reproduced to a larger scale such that it is 30 in. or 36 in. long, the end rotations can then be greatly increased, and the testing is a simple and practical matter.

Assume that this second model, which may be designated as the moment model, is proportioned so that the width scale is the same as in the frame model; but that the longitudinal scale is increased so that m-units of length in the moment model represent one unit of length in the frame model. The moment and frame models are cut from the same sheet material and, therefore, have the same modulus of elasticity. The $\frac{M}{I}$-diagrams in Fig. 12(c), for the two models subjected to numerically equal end moments, M_1 and M_2, would be similar in every respect since the moment of inertia at corresponding sections is equal.

The end rotation, α, for the frame model is the moment of the area under the $\frac{M}{I}$-diagram about Point B, divided by $E\,L$; that is,

$$\alpha = \frac{\int_B^A \frac{M}{I}\,dx\,x}{E\,L} \quad \ldots\ldots\ldots\ldots\ldots\ldots (15a)$$

Likewise, the rotation, α', for the moment model for the same end moments, M_1 and M_2, is:

$$\alpha' = \frac{\int_B^A \frac{M}{I}\,(m\,dx)\,(m\,x)}{E\,(L\,m)} \quad \ldots\ldots\ldots\ldots\ldots\ldots (15b)$$

or the end rotation, α', of the moment model is m times larger than the rotation, α, of the frame model.

Sometimes it is desirable to use a different width scale for the moment model. For instance, if the moment of inertia at corresponding sections is represented by a width of 0.500 in. in the frame model and 0.250 in. in the moment model, the moment of inertia of the frame model is then eight times larger than that of the moment model at corresponding sections; hence, from Equations (15), $\alpha' = 8\, m\, \alpha$.

The precision can be increased if larger rotations are induced in the moment model; for instance, if α' and β' are both doubled, the frame moments, M_1 and M_2, will be one-half the moments applied to the moment model. The following example will further illustrate the method: The moment indicator of 4-in. gage length is attached to a member with a straight axis (see Fig. 12(*a*)). The width of the member varies but is symmetrical within the gage length. The relative moments, y_1 and y_2, of the indices at the third points (Fig. 12(*d*)) are zero and 0.0050 in., respectively. By Equations (14), the rotations, α and β, of the frame model are: $\alpha = \frac{0 + 0.0050}{4} = 0.00125$ radian; and, $\beta = \frac{2(0.0050) + 0}{4} = 0.00250$ radian.

The moment model is made 32 in. long, or eight times longer than the gage length of the frame model, and the width scale is unchanged. The corresponding end rotations to be induced in the model moment are: $\alpha' = m\, \alpha = 8 \times 0.00125 = 0.010$ radian; and, $\beta' = m\, \beta = 8 \times 0.00250 = 0.020$ radian. To increase the precision, rotations of $\alpha' = 0.020$ radian and $\beta' = 0.040$ radian will be used so that the frame moments will be one-half those of the moment model.

The moment model is rigidly clamped to the gage arms, as shown in Fig. 11. These arms pivot about a pin or ball-bearing and carry a pointer 10 in. from the pivot. The rotation is thereby magnified so that it is easily read on a scale of 100 divisions per in. The normal readings of both scales for the unstressed position of the moment model are recorded (see Fig. 13(*a*)) and then with thumb-screws the left arm at Point A is rotated clockwise 0.020 radian so that its pointer deflects 0.200 in. The right arm at Point B rotates freely 0.0135 radian (see Fig. 13(*b*)). A longitudinal pull must now be applied to the right arm to increase the counter-clockwise rotation, β', to 0.040 radian.

Instead of adjusting the pull until this exact rotation is secured, longitudinal pulls of a 1.54-lb weight acting 8 in. from the pivot, first on the pointer end of the right arm and then on the opposite end of the right arm, were applied. The right arm rotated 0.0235 radian counter-clockwise and then 0.0230 radian clockwise. (Fig. 13(*c*)), or an average rotation per inch-pound of moment of $0.0465 \div 24.62 = 0.00189$ radian. Therefore, to increase the rotation of the right arm from 0.0135 to 0.040 radian a counter-clockwise moment of 14.00 in-lb is required (Fig. 13(*f*)). Consequently, a counter-clockwise moment of 7.00 in-lb acts on the frame model at the right end of the gage length.

The process is now reversed. The right arm at Point B is rotated 0.040 radian with thumb-screws and the left arm at Point A freely rotates 0.0278 radian (Fig. 13(*d*)). A longitudinal pull must now be applied so as to reduce the left arm rotation from 0.0278 radian to 0.0200 radian. As before, a longitudinal pull of 12.32 in-lb of moment acting first clockwise and then counter-clockwise causes a rotation of 0.0460 radian, or 0.0187 radian per in-lb of moment (Fig. 13(*e*)). Then, by proportion, a counter-clockwise moment of 4.17 in-lb decreases the rotation to 0.020 radian (Fig. 13(*f*)). The corresponding moment, M_1, on the left end of the frame-model gage length is 2.08 in-lb, counter-clockwise.

FIG. 13

The entire procedure is quite similar to the experimental determination of the elastic constants described elsewhere by the writer.[9] Note that no attempt is made to adjust the moments until the exact rotations, α' and β', are secured. In this way the tedious balancing of the weights simultaneously on each arm is eliminated. If the moment model has a curved axis the procedure followed in the foregoing example must be modified because the rotations due to the longitudinal pulls are dependent upon the kind of stress set up in the moment model.

The pivoting of the moment model so that in effect it is a hinged beam is a departure from perfect similitude. However, the writer has found that the model acts as if it were simply supported, and the end rotations are proportional to the longitudinal pulls over a large range. If one is concerned with friction about the pivot or in the ball-bearing pulleys used for the longitudinal pulls, a constant-section moment model could be tested to calibrate the apparatus for all time.

By an obvious extension of the foregoing method, the moments can be determined for the case of loads acting within the gage length of the moment indicator. Some engineers will prefer the calculation of the moments, M_1 and M_2, to this simple experimental test. A summation process treating the diagrams as trapezoids, similar to the method proposed by George E. Large,[10] Assoc. M. Am. Soc. C. E., will expedite this work.

---

[9] "Fixed End Moments by Cardboard Models," by W. J. Eney, *Engineering News-Record,* December 12, 1935.

Otto Gottschalk,[11] Esq. (by letter).—As its name implies, the moment indicator permits the abstract analysis of stresses, but, without proper and direct reference to actual structures. In dealing with abstract stresses, the same as with abstract mathematics, the investigator frequently derives beautiful and harmonious results, which then require mechanical interpretation. The moment indicator is such a device, and the author's optimism is understandable. However, the writer feels a certain skepticism regarding a few aspects of the problem. In 1937,[12] the writer emphasized the inconsistency and confusion inherent in the practice of analyzing structures mathematically, in terms of abstract stresses, as if those stresses, themselves, were part of the structure. Unfortunately, this fundamental fallacy is being extended to mechanical analysis with equally fallacious results.

In mechanical stress analysis, the model generally is loaded and the bending moments are computed from the measured rotation of the tangent to the deflection curve. In mechanical structural analysis (as distinct from stress analysis), the model is subjected to a unit displacement or rotation at the section being studied. The deformation of the model results in a physical graph of the influence line on a scale, such that the ordinates can be read at the places where the loads are acting. The latter is the correct approach and is the basis of the Beggs deformeter gage mentioned by the authors.[4]

The authors have developed valuable formulas for correcting errors in determining tangents. Rigid exactness of individual tangents, however, depends so much upon perfect homogeneity that the slightest microscopic imperfection in the material or the device clamped upon it will produce errors which are magnified still more by levers and light rays. The use of metallic devices and a relatively soft model material (the true homogeneity of which can be only surmised) would certainly require a degree of precision control that cannot be maintained outside of permanent and special laboratories.

On the other hand, ordinates can be made relatively large by mechanical devices, and quite in accord with abstract theories. They may be considered as the sums of individual deformation, in which local errors or variations are counterbalanced. Perhaps that is the mechanical explanation for the fact that tangent methods of analysis have failed to compete with mechanical methods involving ordinate reading. Although it certainly seems to be a favorable characteristic of the moment indicator that it does not involve the reading of tangent changes, but merely the relation between such changes, this in itself does not guarantee that errors in observing two tangents, relatively, may not be cumulated. The usefulness of any instrument for mechanical analysis is impaired if the instrument requires microscopic reading. This fact in itself tends to take the instrument out of the hands of the analyst and place it into the care of some subordinate or assistant. In the analysis of a special structure of some magnitude it might be justifiable to spend the time cutting and investigating five or ten separate models in order to compare the consistency of results; but for daily routine, it will generally be considered an unjustified burden on the designing staff. The statement in the paper to the effect that the moment indicator requires less manipulative skill than other available methods of mechanical analysis, capable of giving comparable accuracy, is a sweeping one to which much can be said in refutation.

[10] "Analysis of Continuous Frames by Distributing Fixed-End Moments," by Hardy Cross, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 96 (1932), p. 101.

[11] Buenos Aires, Argentine Republic.

[12] "Structural Analysis Based Upon Principles Pertaining to Unloaded Models," by Otto Gottschalk, *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 1019.

For the past one hundred years or more, the entire general theory of statics has been submerged in a veil of mystery by a mass of artificial, intricate mathematical functions of stress. The effect has been to obscure the simple geometrical relation that can be observed by eye. Similarly, in mechanical analysis, the present tendency is to solve structural problems by microscopic examinations which can be visualized macroscopically, more easily and more efficiently. To demonstrate his point, the writer must refer to a device first described in 1926.[13] Similar devices for studying the effect of vertical loads,[14] and for wind stresses,[15] have been described by the writer subsequently. These devices have demonstrated how the theory of statics may be simplified fundamentally by a geometrical interpretation of the visible natural behavior of the given structure.[12] A third fundamental application of the splines and metal clamps recommended by the writer is to the analysis of the structural element with which the designer deals every day. The basic principles underlying the writer's views on this subject have been demonstrated a number of times. The fundamental operations for a structural analysis may be demonstrated briefly by reference to Fig. 14, which is a continuous beam of constant cross-section. With the load shown in Fig. 14(*a*), only a single unit displacement is required to supply the influence line of the reaction R_c in Fig. 14(*b*) and the shear effect, F_E, shown in Fig. 14(*c*). To the left of Point *A*, in Fig. 14(*a*), a load P_1 is acting on a cantilever for which the influence line is the tangent of the curve at Point *A*. When Beams *A B C D* in Fig. 14(*a*) are fixed at Point *A*, the influence line is found by simply lifting the extended end beyond Point *A*, until the tangent at Point *A* is horizontal, as shown by the dotted line in Fig. 14(*a*). Fig. 14(*d*) demonstrates how the influence line for the bending M_F, at Point *F*, is obtained by joining two similar splines by a standard moment clamp and running these lines through the points of support until the apex of one clamp rests below Point *F*. Without using any special degree of precision, and independent of local conditions, the observed result of this analysis is well within 3% of those found by theoretical computations. The same degree of accuracy will be obtained for reactions and shears (Figs. 14(*b*) and 14(*c*)) by applying two transverse displacements equal to one-half unit, without moving the splines horizontally; that is, the support at Point *A*, or at Points *A* and *B*, respectively, is first lifted and then lowered through one-half unit displacement. It should be evident that results obtained in this manner will require less time than would be necessary even to adjust microscopes. When the section of a beam varies in adjacent spans, splines may be added or the spans of the model may be reduced accordingly.

FIG. 14.—STRUCTURAL ANALYSIS AND STRESS CALCULATION OF A CONTINUOUS BEAM

The system is applicable equally to complex frames in steel or reinforced concrete. It can be applied to typical tunnel cross-sections, and to other common elements such as are encountered daily in the modern structural engineering office. No promoters of mechanical equipment for structural analysis should lay claim to merit unless their device can be made to show this range of practical usefulness.

In general, the authors are to be commended for their thorough investigation of model material, and for the formulas introduced to determine necessary corrections. Furthermore, by fastening the moment indicator to the members of the model instead of incorporating it as a part of the member, the authors have, in principle, solved the complex problems of handling. The writer feels, however, that the authors have not maintained a sufficiently clear distinction between the fundamental concept of a mechanical structural analysis, and a mechanical stress analysis as defined roughly in this discussion. The authors have confined themselves to the latter, whereas the writer, by experience, is an advocate of the former.

ARTHUR C. RUGE,[16] ASSOC. M. AM. SOC. C. E., AND ERNST O. SCHMIDT,[17] ESQ. (by letter).—The writers are grateful for the valuable discussions contributed by Messrs. Wilbur, Eney, and Gottschalk. It is particularly gratifying to note that the original study has led to further research and to new instrumental approaches to some of the problems involved.

---

[16] Asst. Prof., Eng. Seismology, Mass. Inst. Tech., Cambridge, Mass.

[17] Asst., Dept. of Civ. and San. Eng., Mass. Inst. Tech., Cambridge, Mass.

Professor Wilbur's discussion develops a number of important points, particularly with regard to secondary stress measurement. The improvement in attaching the levers so as to avoid the shear correction is excellent, and the introduction of a magnifying lever should make for increased efficiency in working with rigid frames as well as in secondary stress applications. The successful use of the spring balance arrangement in conjunction with the moment indicator for secondary stress investigation should encourage others to follow in this interesting and important field of model study; the writers are not aware of any other practical technique for measuring secondary stresses in models with accuracy.

In his discussion of the method of handling the unbalanced joint moments in secondary stress models, Professor Wilbur presents an excellent solution to this problem which is, of course, bound to arise in all such studies, regardless of the method used for measuring moments. The new type of moment indicator, shown in Fig. 10, is an interesting and clever development of the general concept and has obvious points in its favor which would seem to justify a careful study of its possibilities.

Professor Eney contributes an ingenious and elegantly simple method of dealing with the application of the moment indicator to members of variable section. It seems to the writers that observation of the two end rotations with both ends pinned, for a moment applied first at one end and then at the other, might be somewhat faster, in spite of the two simultaneous equations involved. However, Professor Eney has probably found good reasons for adopting his method of observation.

Mr. Gottschalk unfortunately errs in assuming that the authors are "promoters of mechanical equipment for structural analysis." The writers are glad of the opportunity to make it clear that their interest here is solely in the research and engineering aspects of model study and not in the commercialization of their device. The moment indicator is purposely not patented, though it is doubtless patentable, the aim of the writers being to make this easily built and inexpensive tool available to the profession and to encourage thought in a new field of model instrumentation. Most of Mr. Gottschalk's objections were answered in advance in the fourth paragraph of the "Introduction," which the authors here wish to emphasize.

The argument advanced by Mr. Gottschalk to the effect that the basis of the Beggs and Gottschalk methods is "the" correct approach could be argued at length, but the writers prefer to think of it as "a" correct approach—one of many possible approaches. Incidentally, the suggestion of the advisability of building "five or ten separate models in order to compare the consistency of results" is obviously no more applicable to moment indicator work than to analysis by any other method.

Under the heading "Further Considerations," the writers expressed their belief that the most valuable application of the moment indicator may be to secondary stress study. With the increased magnification suggested in the original paper and discussed by Professor Wilbur, the indicator opens a field of model analysis which has long lain dormant for want of effective instrumentation.

LATERAL EARTH AND CONCRETE PRESSURES

BY LAZARUS WHITE[1] AND GEORGE PAASWELL,[2]
MEMBERS, AM. SOC. C. E.

WITH DISCUSSION BY MESSRS. A. E. CUMMINGS, ROBERT G. HENNES, ROBERT F. LEGGET, CHARLES TERZAGHI, JACOB FELD, M. G. SPANGLER, RAYMOND D. MINDLIN, D. P. KRYNINE, DAVID A. MOLITOR, RALPH W. STEWART, AND LAZARUS WHITE AND GEORGE PAASWELL.

SYNOPSIS

The former Committee of the Society on Earths and Foundations, in conjunction with its studies of the distribution of vertical pressures beneath foundations, assigned to the writers, as a Sub-Committee, the study of lateral earth pressures. This paper is a result of such a study. It has long been recognized that the classic methods of analyzing lateral pressures as developed by Coulomb and Rankine were extremely limited in practical application and many attempts have been made to reshape the classic analysis to bring the theory into better consonance with practice. The writers feel that it is better to discard the classic method entirely, and start from the fundamental laws of the theory of elasticity, as had been done with recognized success in the study of the distribution of vertical pressures. The mathematical work and resulting equations are not as simple as the writers would desire, but it is hoped that further study and application of the methods outlined herein will lead to simplifications without loss of rigor. The labor of using the somewhat involved equations is lightened by the tables presented herewith. It is believed that not only are more correct values determined, but a much better understanding may be had of the phenomena attendant upon the three phases of the problem of lateral earth pressures.

INTRODUCTION

The science of soil mechanics has made rapid strides in the decade, 1928 to 1938, in the analysis of foundation problems. The formulas developed by

Boussinesq[3] have proved to be extremely valuable in this connection and the writers have used them in the study of lateral pressures upon earth-sustaining structures. For more than a century many attempts have been made to reconcile actual problems to formulas based upon artificial and non-existent soil types. The writers feel that these attempts are futile and that the engineering terminology identified with them is no longer of real significance.

Soils possess sufficient elastic properties to permit the application of the theory of elasticity in solids to lateral earth pressures. There are three fundamental phases of the analysis of lateral pressure: (I) The lateral pressures induced upon a sustaining structure of sufficient rigidity to prevent fracture of the bank; (II) the lateral pressures induced upon a wall when movement of the wall is sufficient to permit the formation of fracture surfaces in the bank; and (III) the lateral pressures induced upon a wall due to a surface loading. It is seen that only for Phase II have the classic theories of Coulomb and Rankine had any coherence and practical application. Charles Terzaghi, M. Am. Soc. C. E., has given an interesting discussion on this aspect of the problem.[4]

The writers feel that the ever-important question of the pressures developed in forms due to concrete may find a solution along the lines developed for lateral pressures. Although the mathematical treatment may seem complex to those who seek a simple "rule-of-thumb" expression, the formulas as derived are comparatively simple.

Notation.—The symbols used in this paper are defined where they first appear and are assembled for reference in the Appendix.

PHASE I

In Phase I it is assumed that the wall is sufficiently rigid so that the sustained earth bank will not develop fracture surfaces. When an earth mass exerts a lateral pressure upon a sustaining structure this structure is distorted. Since the earth mass itself possesses elasticity, the yielding of the sustaining structure permits a lateral yielding of the earth mass toward the wall or sheeting. This lateral yielding is accompanied by a reduction in the lateral pressures. If the wall is a composite one, comprising members of varied rigidity, the less rigid will yield more, with release of pressure upon them, the more rigid ones finally taking the greater part of the pressure. The distortion of the structure may be small, and yet the re-arrangement and reduction in pressures may be very marked. In the illuminating series of experiments conducted by Professor Terzaghi, at the Massachusetts Institute of Technology, it was found that a movement of the experimental wall as little as 1 mm caused a reduction of 75% in the pressures induced upon the wall. If the movement of the wall persists so that fracture surfaces are developed, it has been found that the general shape of such fracture is as shown in Fig. 1. The surface of fracture is generally recognized as a shear failure surface. At some future time the writers hope to present the development of the pressures due to this shear failure based upon the assumption that the failure surface is a cosine curve. It is important to remember that this characteristic failure surface with the emergent break at the surface, approximately distant from the wall one-half the depth of wall, is independent of the type of ground, the only requisite for its appearance being a sufficiently flexible wall, or a yielding foundation under the wall. The general ground movement due to a shear failure in saturated soils such as clay and silts is a separate phenomenon not discussed in this paper.

Sheeting and bracing, when properly designed and installed, come within Phase I. The system is one of varied rigidity—the sheeting being the most flexible, the wales next, and, finally, the braces the most rigid. The relative yielding of these component parts of the sustaining structure produces an accumulation of stress zones at the more rigid points. The pressures induced upon these component parts may be viewed as derived from soils of three characteristic properties each producing a system of lateral pressures of increasing intensity going from the sheeting to the wales and finally to the braces or tie-rods.

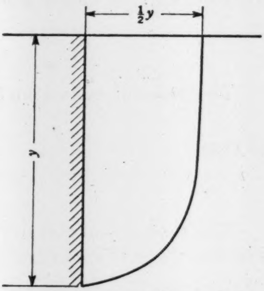

Fig. 1.—Typical Section of a Fracture Surface

Theory of Design—Sheeting and Bracing

For an elastic solid subject to its own weight alone, the total lateral pressure at any depth, y, below the surface is given by,

$$F = -w\,y\,\frac{\mu}{1-\mu} \qquad \text{.......................(1)}$$

in which μ is the Poisson ratio. The negative sign in Equation (1) indicates a compression. In accord with elastic theory, μ may have any value between 0.5 and -1. If it were greater than 0.5, the material would not resist distortion; and if it were less than -1, it would not resist compression. As a matter of fact it is positive for all known structural materials. For a true liquid, $\mu = 0.5$, and Equation (1) reduces to the hydrostatic law, $F = -w\,y$.

As the theory of lateral pressures involves Poisson's ratio, it may be well to outline, briefly, its relation to the other elastic constants. Assume that a load, P, is applied along the X-axis of a unit cube and is the only force acting upon this solid. Let the resulting strains induced in this solid by the load along the X, Y, and Z-axes be ϵ_e, ϵ_f, and ϵ_g, respectively. If m and n are two, at present, undefined constants, the following equations exist:

$$P = (m + 2\,n)\,\epsilon_e + n\,(\epsilon_f + \epsilon_g) \qquad \text{................(2)}$$

$$0 = (m + 2\,n)\,\epsilon_f + n\,(\epsilon_g + \epsilon_e) \qquad \text{................(3)}$$

and,

$$0 = (m + 2\,n)\,\epsilon_g + n\,(\epsilon_e + \epsilon_f) \qquad \text{................(4)}$$

From these three equations of equilibrium,

$$P = \frac{n\,(3\,m + 2\,n)}{m + n}\,\epsilon_e \qquad \text{.......................(5)}$$

and,

$$\epsilon_f = \epsilon_g = - \frac{m \, \epsilon_e}{2\,(m + n)} \quad \text{(6)}$$

The modulus of elasticity is defined as $E = \frac{P}{\epsilon_e}$, giving a relation between the constants, m and n, and the modulus, E, equal to:

$$E = \frac{n\,(3\,m + 2\,n)}{m + n} \quad \text{(7)}$$

The Poisson ratio is defined by the ratio between axial and lateral strain,

$$\epsilon_f = \epsilon_g = - \mu \, \epsilon_e \quad \text{(8)}$$

so that,

$$\mu = \frac{0.5\,m}{m + n} \quad \text{(9)}$$

The modulus of rigidity or shear (usually denoted by the symbol, G) is the same as the coefficient, n. The three elastic constants, E, G, and μ, are related by:

$$E = 2\,G\,(1 + \mu) \quad \text{(10)}$$

For soils it has been found that μ may vary between $\frac{3}{8}$ and $\frac{1}{6}$, the lower values applying to loose-textured soils and the higher values to clays and, possibly, dense sands. It should be noted that a variation in the value of μ changes only the scale, and not the manner, of the distribution of lateral pressure. A general form of expression for lateral pressure against a sheeted cut may be given as,

$$F = - K\,w\,y \quad \text{(11)}$$

Referring to Equation (1) K may receive a maximum value of 0.6 and a minimum value of 0.2. A rational method of designing sheeting and bracing would be to use the maximum value of K for the more rigid members of the supporting system and a much smaller one for the flexible sheeting.

Permanent structures, such as retaining walls, sub-surface structures, abutments, etc., require careful study as to possible movement before determining the maximum design pressures. Walls of uniform rigidity will move under the initial pressure. A drop in pressure ensues as the material supported by the wall expands elastically behind the wall. The pressure may again build up slowly, causing a further movement of the wall with another cycle of elastic expansion, until sufficient movement has occurred to cause fracture surfaces and possible slides. An analysis of these movements with their possible limitations by design of wall and foundation may indicate economies of design by using lower pressure coefficients. A further complication may enter should the material be saturated and should the foundation itself be wet, particularly if such hydraulic conditions may permit a loss of sustaining power due to the upward flow of water beneath the foundation.

LATERAL PRESSURES DUE TO SURFACE LOADS

The characteristic distribution of lateral pressures along a vertical surface due to a surface load is shown in Fig. 2. The maximum intensity is at the surface, diminishing rapidly with the depth. Any effect of the introduction of a free vertical surface upon the analysis is ignored. It is assumed that the neglect of this factor introduces no serious error.

The simplest problem is that of a single load, analyzed by Boussinesq.[5] (The formulas usually attributed to Boussinesq are more properly termed the Boussinesq-Hertz formulas.) As loads are generally spread over large areas it becomes necessary to partition the area into smaller ones, treating each as a single load and adding the total to secure the composite effect. However, it is possible, by an analysis developed by A. E. H. Love,[6] to obtain, directly, the effect of a rectangularly distributed surface load. The formulas are more cumbersome, but are in a usable form entailing less work than the partitioning process; and they remove the uncertainty involved in a failure to partition the area into small enough units. When the loaded area is long and narrow, the strip method may be used—that is, the method of plane sections. Fairly simple formulas result for this case. To complete the analysis for strip loading, equations developed by Professor N. M. Guersevanoff for irregular types are added.[7]

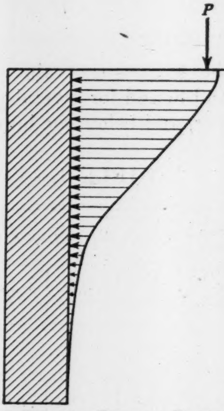

FIG. 2.—TYPICAL DISTRIBUTION OF LATERAL PRESSURES AGAINST A VERTICAL FACE DUE TO A SURFACE LOAD

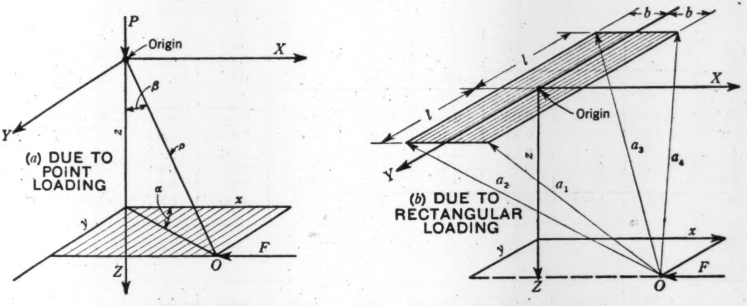
Point Load.—Referring to Fig. 3(*a*),

$$F = -k\frac{P}{\rho^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (12)$$



(*a*) DUE TO POINT LOADING

(*b*) DUE TO RECTANGULAR LOADING

FIG. 3.—CO-ORDINATE SYSTEM FOR LATERAL PRESSURES

in which P is the intensity of surface loads, and k is a constant, expressed by:

$$k = \frac{1}{2\pi}\left[3\sin^2\beta\cos\beta\cos^2\alpha - (1 - 2\mu)(\cos\beta - U)\right] \ldots\ldots (13a)$$

---

[5] See "Applications des Potentials," by Boussinesq.

[6] *Philosophical Transactions*, Series A, Vol. 228, 1929.

[7] These equations developed by Prof. Guersevanoff were taken from a brochure by him sent to the writers. The brochure was lost in a fire and the writers are unable to refer to the exact title and date of publication.

and, U is a substitution factor:

$$U = \frac{1}{1 + \cos\beta} - \frac{\sin^2\beta\,(2 + \cos\beta)}{(1 + \cos\beta)^2}\cos^2\alpha \ldots\ldots\ldots\ldots (13b)$$

Table 1 gives the value of k for a range of values of the co-ordinate angles, α and β, and for several values of the Poisson ratio, μ. Values of k above the upper, and below the lower, heavy lines denote tensile stresses.

Rectangular Loading.—Referring to Fig. 3(*b*),

$$F = \frac{P}{2\pi}[2\mu A - (1 - 2\mu) B - z C] \ldots\ldots\ldots\ldots\ldots (14)$$

in which,

$$A = -[2\pi - (q_1 + q_2 + q_3 + q_4)] \ldots\ldots\ldots\ldots\ldots (15a)$$

$$B = (m_1 + m_2 + m_3 + m_4) - (n_1 + n_2 + n_3 + n_4) \ldots\ldots (15b)$$

and,

$$C = -\left\{\frac{x_1}{k_1^2}\left[\frac{y_1}{a_1} + \frac{y_2}{a_4}\right] + \frac{x_2}{k_4^2}\left[\frac{y_1}{a_2} + \frac{y_2}{a_3}\right]\right. \ldots\ldots\ldots\ldots (15c)$$

$$x_1 = b - x \ldots\ldots (16a) \qquad y_1 = l - y \ldots\ldots (16c)$$

$$x_2 = b + x \ldots\ldots (16b) \qquad y_2 = l + y \ldots\ldots (16d)$$

and,

$$k_1^2 = x_1^2 + z^2 \ldots\ldots (17a) \qquad k_3^2 = y_2^2 + z^2 \ldots\ldots (17c)$$

$$k_2^2 = y_1^2 + z^2 \ldots\ldots (17b) \qquad k_4^2 = x_2^2 + z^2 \ldots\ldots (17d)$$

and,

$$\cos q_1 = \frac{x_1 y_1}{k_1 k_2} \ldots\ldots (18a) \qquad \cos q_3 = \frac{x_2 y_1}{k_2 k_4} \ldots\ldots (18c)$$

$$\cos q_2 = \frac{x_1 y_2}{k_1 k_3} \ldots\ldots (18b) \qquad \cos q_4 = \frac{x_2 y_2}{k_3 k_4} \ldots\ldots (18d)$$

If x or y is greater than b or l so that $\cos q$ is negative, substitute for q, in Equation (15a), the value, $\pi - q$. All angular values are in circular measure:

$$\tan m_1 = \frac{y_1}{x_1} \ldots\ldots (19a) \qquad \tan m_3 = \frac{y_1}{x_2} \ldots\ldots (19c)$$

$$\tan m_2 = \frac{y_2}{x_1} \ldots\ldots (19b) \qquad \tan m_4 = \frac{y_2}{x_2} \ldots\ldots (19d)$$

and,

$$a_1^2 = k_1^2 + y_1^2 \ldots\ldots (20a) \qquad a_3^2 = k_4^2 + y_2^2 \ldots\ldots (20c)$$

$$a_2^2 = k_4^2 + y_1^2 \ldots\ldots (20b) \qquad a_4^2 = k_1^2 + y_2^2 \ldots\ldots (20d)$$

and,

$$\beta_1 = \frac{z}{a_1} \ldots\ldots (21a) \qquad \beta_3 = \frac{z}{a_3} \ldots\ldots (21c)$$

$$\beta_2 = \frac{z}{a_2} \ldots\ldots (21b) \qquad \beta_4 = \frac{z}{a_4} \ldots\ldots (21d)$$

and,

$$\tan n_1 = \beta_1 \tan m_1 \ldots (22a) \qquad \tan n_3 = \beta_2 \tan m_3 \ldots (22c)$$

$$\tan n_2 = \beta_4 \tan m_2 \ldots (22b) \qquad \tan n_4 = \beta_3 \tan m_4 \ldots (22d)$$

If $\tan m$ or $\tan n$ appears negative, use negative values for these angles as derived from Equations (22).

This analysis for rectangular loads fails for points directly below the corners of the load. Determinate values may be found, however, for neighboring points and should serve the purpose.

TABLE 2.—LATERAL PRESSURES AT VARIOUS POINTS BELOW A LOADED AREA

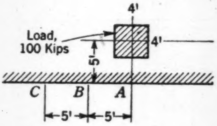
In applying the Boussinesq equations to spread footings, it is not easy, for points close to the loaded surface, to arrive at a proper sub-division for a fairly accurate result. Equations (14) to (22) give the correct theoretical result. For comparative purposes, the data in Table 2 show the values of the lateral pressures at certain points below a loaded area as derived by Equation (14) and then show the derived pressures as obtained by using the Boussinesq equations for single and subdivided loads for the same area. The applied loading is taken as unit intensity.

Table 3 shows the distribution of lateral pressures under a pier footing. The total load on the pier is 100 kips, giving a load of 6.250 kips per sq ft.

TABLE 3.—DISTRIBUTION OF LATERAL PRESSURES, IN KIPS* PER SQUARE FOOT UNDER A PIER FOOTING



Distance below base of footing, in feet	Interval, in feet	POINT *A*		POINT *B*		POINT *C*	
		Pressures for the Following Values of Poisson's Ratio, μ:					
		0.3	0.4	0.3	0.4	0.3	0.4
0		....	....	....	....	....	....
2	2	0.38	0.45	0.09	0.11	0.03	0.02
5	3	0.26	0.30	0.09	0.12	0.03	0.02
8	3	0.04	0.06	0.05	0.06	0.01	0.01
13	5	0.01	0.01	0	0.02	0	0
18	5	0	0	0	0.01	0	0

* 1 kip = 1 000 lb.

The lateral pressures have been found on the assumption of a single concentration at the center of the pier. As a check, using Equation (14) for Point $x = 5$; $y = 0$; $z = 2$, with $\mu = 0.3$; and $F = 0.38$. For $\mu = 0.4$, $F = 0.47$, which shows that the assumption of a single concentration is accurate.

Strip Loading.—For a continuous strip of loaded area, such as a wall, railroad track, etc., a typical section may be taken, and the lateral pressure from this section is given by:

$$F = -\frac{p}{2\pi}\left[2(\beta_1 - \beta_2) + \sin 2\beta_1 - \sin 2\beta_2\right] \ldots\ldots\ldots (23)$$

The angles are in circular measure. Table 4 shows the distribution of pressures under the center, edge, and a distance of 10 ft away from a strip, 20 ft wide, loaded with unit loading. This type of loading is important in the analysis of the effect of neighboring foundation loads upon sub-surface structures and the use of Equation (23) obviates the application of "rule-of-thumb" methods of determining the zone of disturbance and calculation of lateral pressures from equivalent "surcharge" effects.

TABLE 4.—DISTRIBUTION OF LATERAL PRESSURES, IN KIPS* PER SQUARE FOOT, UNDER STRIP LOADING

5		0.45	0.35	0.17	30		0.01	0.04	0.09	80		....	....	....

* 1 kip = 1 000 lb.

Point Load.—If the strip is narrow, or points are selected at a distance from the strip (see Fig. 4(*a*)) a simple formula gives the lateral pressure,

$$F = \frac{2\,P\,y\,x^2}{\pi\,\rho^4} \qquad (24)$$

Trapezoidal Loading.—For the loading shown in Fig. 4(*b*):

$$F = \frac{2\,y}{\pi}\,(b_1\,M + b_2\,N) + \frac{1}{\pi}\,(b_1\,x + p_0)\tan^{-1}\frac{2\,b_2\,y}{u^2} \qquad (25a)$$

$$p_0 = \frac{1}{2}\,(p_a + p_b) \qquad (25b)$$

$$b_1 = \frac{1}{2\,b_2}\,(p_b - p_a) \qquad (25c)$$

$$M = \log_e \frac{\rho_1}{\rho_2} \qquad (25d)$$

$$u^2 = x^2 - b_2^2 - y^2 \qquad (25e)$$

and,

$$N = \frac{2\,b_1\,x\,y^2 + b_1\,x + p_0)\,u^2}{u^4 + 4\,x^2\,y^2} \qquad (25f)$$

Triangular loading, a special case of trapezoidal loading (see Fig. 4(*c*)), is expressed by,

$$F = -\frac{j}{\pi}\left[y\,Q + x\left(\tan^{-1}\frac{y}{x-t} - \tan^{-1}\frac{y}{x}\right) + y\,t\,\frac{x-t}{(x-t)^2+y^2}\right] \quad \text{..(26a)}$$

and,

$$Q = \log_e \frac{(x-t)^2+y^2}{x^2+y^2} \quad \text{.................(26b)}$$

FIG. 4.—LATERAL PRESSURES; VARIOUS TYPES OF LOADING

Parabolic Loading.—For the loading shown in Fig. 4(*d*):

$$F = -\frac{p_0}{\pi\,b_2^2}\left[(3\,y^2 + b_2^2 - x^2)\tan^{-1}\frac{2\,b_2\,y}{u^2} - 4\,x\,y\,M - 2\,b_2\,y\right] \quad \text{..(27)}$$

in which u^2 and M are as defined by Equations (25*d*) and (25*e*).

The lateral pressures, as given by Equations (23) to (27), are assumed to be distributed along rigid supports yielding no more than the elastic material which it supports. Should the supporting structure be a composite one, such as temporary sheeting and bracing, the same cycles of elastic expansion and loading take place as described herein under the heading, "Theory of Sheeting and Bracing," and the more rigid parts of the sustaining system gradually take up the bulk of the loading.

CONCRETE PRESSURES

The construction of high concrete piers for the Alton (Ill.) Dam, on the Mississippi River, afforded an opportunity to make a series of readings to ascertain pressures exerted by green concrete on forms. The pressures were computed from extensometer readings taken on tie-rods supporting the forms. The tie-rods were free to slip inside boiler-tubes which acted as separators for the form panels. Two pressure curves, derived from the extensometer readings, are shown in Fig. 5. The translation of extensometer readings to pressures is not given herein and is based upon an assumed distribution of pressure from sheeting panel to stud and wales and, in turn, to tie-rod.

The experimental curves have suggested to the writers that the methods outlined previously for the determination of lateral pressures may prove serviceable in analyzing concrete pressures.

A form of fairly standard construction is shown in Fig. 6. The problem is to trace the concrete pressures at some elevation, Plane AA, as the newly poured concrete rises in the form, above the level, AA. From Point A to some height, h, the pressures at Point A are due to the weight of the concrete mass as expressed by Equation (6). The value of the Poisson ratio, μ, decreases from that of a pure liquid at Point A to the value of concrete when set. At the height, h, it is assumed that the concrete at Point A has taken a set and the pressures at that point are then due to a superimposed load upon a free surface which itself rises as the concrete takes a set above Level A. As the pressures gradually decrease in accordance with this condition, the theoretical curves should follow that shown in Fig. 5. Actually, however, the setting of the concrete prevents the tie-rod from returning to its initial length; it can simply recover the distortion it has undergone since the concrete passed Level h. The curves of pressure obtained experimentally take this shape and the foregoing analysis is an attempt to explain the result.

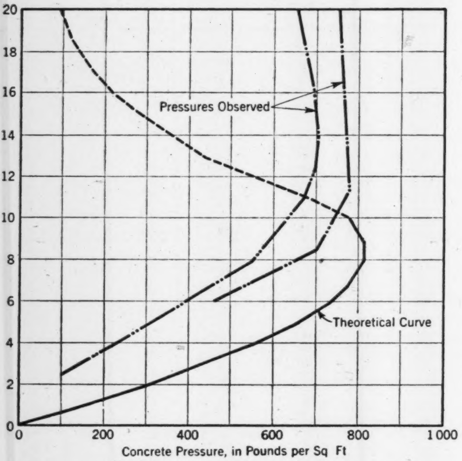

FIG. 5.—PRESSURE EXERTED BY NEWLY FORMED CONCRETE

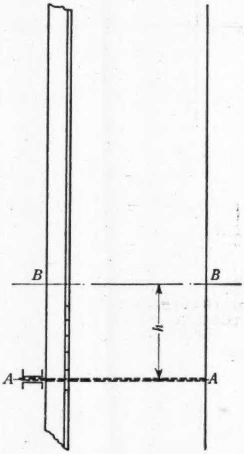

FIG. 6

To give mathematical form to the foregoing reasoning it may be assumed that the change in the Poisson ratio occurring in the first stage of the concrete pressures is given by an empirical relation,

$$\mu = \mu_0 + c\,t^2 \qquad (28)$$

in which t is the time the concrete has been in the form at Elevation AA (Fig. 6). If μ is assumed to have the liquid value at time, $t = 0$; and if it finally attains a value of 0.25 when the set has occurred (or, for time, $t = t_0$), the relation becomes,

$$\mu = \frac{1}{2} - \frac{t^2}{6\,t_0^2} \qquad (29)$$

and Equation (6) may be written in the form,

$$F = w\,h\,\frac{3 - U\,h^2}{3 + U\,h^2} \qquad (30)$$

in which,

$$U = \frac{1}{H^2\,t_0^2} \qquad (31)$$

since $h = H\,t$. The maximum pressure occurs for a value of $h = 0.84\,H\,t_0$ and, at this point, the maximum pressure becomes,

$$F = 0.52\,w\,H\,t_0 \qquad (32)$$

The determination of the pressures when the concrete at Elevation AA has set is taken from the formula for strip loading (Equation (23)). Since the condition is expressed by Fig. 7, the equation may be simplified for this case so that,

$$F = \frac{P_B}{2\,\pi}\,(2\,\beta_0 - \sin 2\,\beta_0) \qquad (33)$$

in which P_B is the weight of the concrete above Plane BB (Fig. 6). Angle β_0 is determined by the width of the form and the distance, z. The weight of concrete, P, will be constant and the variable will be the distance, z. In Fig. 5 the shape of this curve of decreasing pressures is shown dotted.

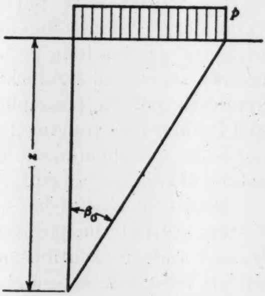

FIG. 7

In the experiments at Alton the weight of the concrete was about 155 lb per cu ft and the level rose in the form at a rate of 2 ft per hr. The time of set was about 5 hr. In the foregoing analysis, therefore, $H = 2$; and, $X_0\,t_0 = 5$. The height for maximum pressure is then 8.4 ft and the maximum pressure, 806 lb. To complete the curve (not of practical significance herein) take $B = 1\,550$ lb and use Equation (33).

Obviously, better fit may be made to the actual observed curve of pressure by "juggling" the empirical relation given by Equation (28), but this mathematical manipulation is not warranted by the conditions of the problem, and the similarity of shape of the curves indicates that the theory possesses some validity and, therefore, seems a better guide to the determination of concrete pressures than the usual assumptions of modified hydrostatic relations.

CONCLUSIONS

The analysis of lateral earth pressures resolves itself into a study of three phases of this problem. The first phase is that of the distribution of pressures along a wall sufficiently rigid or unyielding so that no fracture surfaces appear in the ground. In this case the pressures cause a slight yielding of the wall and a redistribution of pressures appears, tending to concentrate around the more unyielding portions of the supporting system. The pressure systems may be then separated for each system of support using a smaller intensity of pressures for the more yielding portion of the system such as the sheeting and to some extent the wales, and the maximum intensity of pressures for the braces or tie-rods. To accomplish this analysis it is suggested that the soil be assumed to possess a variable Poisson's ratio, the smaller for the sheeting and the highest for the braces. Although this may seem an arbitrary assumption as to physical constants of the soil, it seems at present the most suitable device to use.

The second phase, that of pressures developed when a fracture surface is permitted to develop is discussed very briefly. Only in this phase has the analysis of Rankine and Coulomb any significance. The writers hope to present some numerical examples of pressures developed in actual work in this phase at some later date.

The third phase, that of the distribution of pressures due to a surface load, is covered in extensive mathematical detail. It is hoped that the results given will supersede the usual rule-of-thumb method for determining pressures due to surcharges. It is important to note that the intensity of pressures due to a surface load is a maximum quite near the surface and diminishes rapidly in intensity, a fact quite in contradiction to the usual method of analyzing surcharge loads.

The writers have purposely avoided introducing the terms, "coherent," "granular," "non-coherent," and, finally, "angle-of-repose" or "internal friction." For a long period they have recognized that these terms are misleading and of no significance in discussing lateral pressures. The successful application of the principles of the theory of elasticity to soils, both in theory and in their own practice has convinced them that the road to correct determination of soil phenomena lay in such application and not in futile attempts to extend the classic formulas by modifications of coefficients, and the like.

Finally, it should be stated that almost ten years have elapsed since the writers started the preparation of this paper. Experiments have been performed and observations made on lateral pressures in this period which the writers trust will be brought forth in the course of discussion which may clarify or even refute some of the theory presented.

APPENDIX

NOTATION

The following notation conforms essentially with American Standard Symbols for Mechanics, Structural Engineering and Testing Materials[8] compiled by a committee of the American Standards Association with Society representation, and approved by the Association in 1932:

A = a substitution factor defined by Equation (15*a*);
a = a distance; a_1, a_2, a_3, and a_4 (see Fig. 3(*b*)) are distances to the corners of a rectangular load;
B = a substitution factor defined by Equation (15*b*);
b = breadth; one-half the width of a rectangular load; b_1 and b_2 are defined where they are introduced;
C = a substitution factor defined by Equation (15*c*);
E = modulus of elasticity;
e = base of Naperian logarithms;
F = total lateral pressure per unit of area;
G = modulus of elasticity in shear; modulus of rigidity;
g = acceleration due to gravity;
H = head;
h = height;
I = rectangular moment of inertia;
j = a ratio in Fig. 4(*c*);
K = hydrostatic pressure ratio;
k = a substitution coefficient defined by Equation (13*a*);
L = length;
l = one-half the length of a rectangular load;
M = a substitution factor defined by Equation (25*d*);
m = a constant; m_1, m_2, m_3, and m_4 refer to the corners of a rectangular load;
N = a substitution factor defined by Equation (25*f*);
n = a constant (equal to G); n_1, n_2, n_3, and n_4 refer to the corners of a rectangular load;
P = a load; P_B = the weight of the concrete above Plane BB;
p = pressure per unit area; p_H = intensity of lateral pressure; p_V = intensity of vertical pressure;
Q = a substitution factor defined by Equation (26*b*);
q = a substitution factor defined by Equations (18);
t = setting time for concrete;
U = a substitution factor defined by Equation (31);
u = a substitution factor defined by Equation (25*e*);
w = load per unit volume;
x = distances parallel to the X-axis; x_1, x_2, x_3, and x_4 are distances, x, to the corners of a rectangular load;

---

[8] A.S.A.—*Z* 10*A*—1932.

y = deflection; also distances measured parallel to the Y-axis; y_1, y_2, y_3, and y_4 are distances, y, to the corners of a rectangular load;
z = distances parallel to the Z-axis measured from the base of a footing; z_1, z_2, z_3, and z_4 are distances, z, to the corners of a rectangular load;
α = angular distance to the point of application of Force F, in the XY-plane;
β = half-angle formed under a load, P, by the radius, ρ (Fig. 3(*a*));
δ = unit elongation;
ϵ = strain; for example, ϵ_e, ϵ_f, and ϵ_g in Equations (2) to (6);
θ = angular distance in polar co-ordinates;
μ = Poisson's ratio;
ρ = radial distance in polar co-ordinates.

DISCUSSION

A. E. CUMMINGS,[9] M. AM. SOC. C. E. (by letter).—An interesting analysis of the problem of lateral pressures is contained in this paper. However, from Fig. 2 and the supporting remarks, it appears that the authors have misinterpreted the nature of the horizontal stresses due to surface loads.

Referring to Fig. 3(*a*), the complete representation of stress at the point, *O*, would include three normal stresses and three shearing stresses. For the purpose of this discussion, it is not necessary to consider the shearing stresses. The three normal stresses are:

$$p_z = -\frac{3P}{2\pi}\frac{z^3}{\rho^5} \qquad (34a)$$

$$p_y = \frac{P}{2\pi}\left[-\frac{3y^2z}{\rho^5} + (1-2\mu)\left\{\frac{z}{\rho^3} - \frac{(\rho^2-y^2)(z+\rho)-\rho y^2}{\rho^3(z+\rho)^2}\right\}\right] \qquad (34b)$$

and,

$$p_x = \frac{P}{2\pi}\left[-\frac{3x^2z}{\rho^5} + (1-2\mu)\left\{\frac{z}{\rho^3} - \frac{(\rho^2-x^2)(z+\rho)-\rho x^2}{\rho^3(z+\rho)^2}\right\}\right] \qquad (34c)$$

These stresses are written in rectangular co-ordinates. The plus sign represents tension and the minus sign compression. The subscripts, *x*, *y*, and *z*, refer to the co-ordinate axis with which the stress is parallel. This discussion will concern itself with the stress, p_x, which corresponds to the authors' stress, *F*, in Equation (12).

Fig. 8 represents the *X–Z* plane of Fig. 3(*a*). Line *R S* is the trace on the *X–Z* plane of an imaginary plane which is parallel to the *Y–Z* plane. The unit horizontal stress, p_x, at any point on the line, *R S*, is given by Equation (34*c*). Inspection of this equation does not show whether the stress is tension or compression. However, it is a simple matter to determine the nature of this stress at the point, *T*, which is on the surface of the solid. Substitution of $z = 0$ and $\rho = x$ in Equation (34*c*) gives:

$$p_x = (1-2\mu)\frac{P}{2\pi\rho^2} \qquad (35a)$$

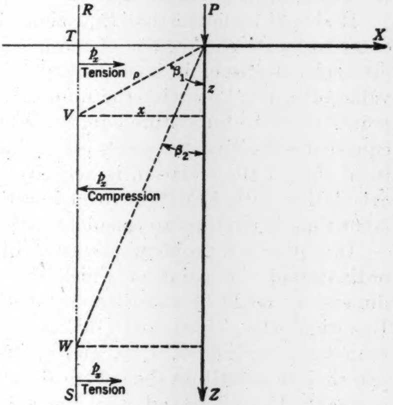

FIG. 8

In a similar manner the nature of this stress at any point on the *Z*-axis may be determined. Substitution of $x = 0$ and $\rho = z$ in Equation (34*c*) gives:

$$p_x = (1-2\mu)\frac{P}{4\pi\rho^2} \qquad (35b)$$

---

[9] Dist. Mgr., Raymond Concrete Pile Co., Chicago, Ill.

Since μ is never numerically greater than 0.5 in any elastic solid, the right-hand sides of Equations (35) are positive for all elastic solids. Stress p_x, therefore, is a tension at the point, T, and at all points on the Z-axis. For an incompressible material ($\mu = 0.5$) Stress p_x becomes zero at the point, T, and at all points on the Z-axis. In elastic materials with μ-values less than 0.5, the stress, p_x, on the line, $R\,S$, is a tension from the surface down to some point, V. At the point, V, the stress changes sign and becomes a compression. It is a compression down to the point, W, where it again changes sign and becomes a tension.

The location of the points, V and W, can be determined from Equation (34*c*) by setting the expression in square brackets equal to zero. In the new equation thus obtained, it is necessary to substitute $x^2 = \rho^2 - z^2$ and $\frac{z}{\rho} = \cos\beta$. Reduction of the equation then leads to,

$$\cos\beta + \cos^2\beta - \cos^3\beta - \cos^4\beta = \frac{1 - 2\,\mu}{3} \qquad \text{(36)}$$

It is seen from Equation (36) that the positions of the points, V and W, are determined by the elastic properties of the material. For a given numerical value of μ, the angle, β, can be found by solving the fourth-order equation in $\cos\beta$. When $\mu = 0.2$, Equation (36) has two real roots which are (approximately) $\cos\beta_1 = 0.175$ and $\cos\beta_2 = 0.945$. The other two roots are a pair of conjugate complex numbers which have no physical meaning in this problem. Therefore, in an elastic solid having $\mu = 0.2$, the angle, β_1, is about 80° and the angle, β_2, is about 19 degrees.

It should be noted that Equation (36) applies only in the X–Z plane. In order to locate the regions of tension and compression throughout the three-dimensional space, it is necessary to use Equation (34*c*). The numerical value of μ, together with the numerical values of the co-ordinates of a given point, must be substituted in the equation. If the right-hand side of the equation is positive, the stress is a tension at the given point. When the right-hand side of the equation is negative, the stress is compression. Numerical calculation with Equation (34*c*) is rather laborious although it involves less labor than is required to calculate with Equations (12), (13*a*), and (13*b*).

In a practical problem, the given dimensions would be the rectangular co-ordinates of the point at which the stress was to be determined. These dimensions could be substituted directly in Equation (34*c*). In order to use Equations (12), (13*a*), and (13*b*) it would be necessary to transform the rectangular co-ordinates, x, y, and z, into spherical co-ordinates α, β, and ρ, and then to substitute the spherical co-ordinates in the equations. The writer is unable to understand why the authors chose to handle this rectangular problem in spherical co-ordinates since the method does not simplify the problem in any way.

Furthermore, if it is considered desirable to use angles instead of rectangular co-ordinates, it is much easier to use the direction cosines of the radius vector, ρ, than it is to transform the entire problem to spherical co-ordinates. If β is the angle between ρ and the Z-axis and if ϕ is the angle between ρ and the X-axis, Equation (34c) can be expressed in terms of functions of these angles as follows:

$$p_x = \frac{P}{2\pi\rho^2}\left[-3\cos^2\phi\cos\beta + (1-2\mu)\left\{\cos\beta - \frac{\sin^2\phi}{1+\cos\beta}\right\}\right] \quad (37)$$

It is easy to see that Equation (37) is much less complicated than Equations (12), (13a), and (13b).

In connection with Fig. 2, the authors state that they are ignoring any effect that may be caused by the introduction of the free vertical surface. In effect, this means that the wall in Fig. 2 represents nothing more than the imaginary plane, $R\,S$, in Fig. 8. However, the horizontal stress on the line, $R\,S$, is a tension near the surface, and it changes to a compression at some point, V, below the surface. At the point, W, the stress changes again from a compression back to a tension. Even with the simplifying assumption made by the authors, Fig. 2 does not represent the typical distribution of lateral stress on a vertical plane due to a point load on the surface of the semi-infinite elastic solid.

As far as the actual effect of the free vertical surface is concerned, this problem has been studied both theoretically and experimentally. A theoretical analysis has been published by Raymond D. Mindlin,[10] Assoc. M. Am. Soc. C. E. The same problem has been the subject of considerable experimental investigation conducted by M. G. Spangler,[11] Assoc. M. Am. Soc. C. E. Mr. Mindlin's analysis and Mr. Spangler's experiments indicate that the actual pressure on the back of the wall due to a load at the surface is considerably different from Fig. 2. In other words, it has already been demonstrated that the free vertical surface has a decided effect on the stress distribution so that the authors' assumption about this question was not justified.

It is interesting to note that the authors' equations themselves, disprove the validity of Fig. 2. Table 1 shows that there are regions in the semi-infinite elastic solid where the horizontal stress, F, is a tension. This table also shows that the value of μ determines the amount of the tension and the region in which the tension occurs. Throughout Table 1, the X–Z plane is represented by $\alpha = 0$. In that part of the table which is calculated for $\mu = 0.2$, the stress for $\alpha = 0$ is tension when β lies between zero and 20° and it is also tension when β lies between 80 and 90 degrees. This agrees exactly with the results obtained from Equation (36).

It can also be seen quite easily that Fig. 2 does not represent the characteristic lateral pressure distribution due to the types of loading shown in Fig. 4. Throughout Fig. 4, the ground surface is represented by $y = 0$. By inspection, it can be seen that the substitution of $y = 0$ in Equation (24) will make $F = 0$. In other words, the stress, F, in Fig. 4(a) is zero at the ground surface. Substitution of $y = 0$ in Equations (25a), (26a), and (27) shows that the stress, F, is zero at the ground surface for all the types of loading shown in Fig. 4.

[10] "Pressure Distribution on Retaining Walls," by Raymond D. Mindlin, *Proceedings*, International Conference on Soil Mechanics and Foundation Engineering, Harvard Univ., Cambridge, Mass., Vol. III, 1936, p. 155.

[11] "Horizontal Pressures on Retaining Walls Due to Concentrated Surface Loads," by M. G. Spangler, *Bulletin No. 140*, Iowa Eng. Experiment Station, 1938.

In conclusion, the writer wishes to call attention to an important point in connection with problems of this kind. Aside from the fact that Fig. 2 does not represent the typical distribution of lateral stress on a vertical plane for any kind of surface loading on a semi-infinite elastic solid, there is the question of ignoring the free vertical surface on the assumption that the neglect of this factor introduces no serious error. Most problems in the theory of elasticity can be described as boundary value problems. The problem is usually set up as a differential equation for which a particular solution is determined by the use of certain boundary conditions. With a different set of boundary conditions, the solution of the differential equation may be entirely different. For all the various types of surface loads mentioned in this paper, the authors' equations for F were derived on the assumption that the elastic solid was infinitely deep and that its plane horizontal boundary extended to infinity in both horizontal directions. The solutions of the differential equations were required to satisfy certain conditions at infinity and certain other conditions on the free horizontal boundary. Equations derived for these boundary conditions could not be expected to be valid when a new boundary condition is introduced in the form of a free vertical surface not far from the load. Mr. Spangler's experiments[11] show that the maximum horizontal pressures on the back of the wall could be at least twice as great as those calculated with Equation (12) even in a material having $\mu = 0.5$. For smaller values of μ, Equation (12) gives tensions in certain parts of the stress field but tension could not exist unless the soil were somehow fastened to the back of the wall. These are conditions that should be kept in mind by any one attempting to calculate pressures on retaining walls with the equations in this paper.

ROBERT G. HENNES,[12] ASSOC. M. AM. SOC. C. E. (by letter).—It is important to realize that, as the authors indicate, Equations (1) to (11) are primarily intended for the design of sheeting and bracing. When applied to permanent rigid structures, such as underground tanks and other sub-surface construction, in soils subject to elastic expansion and contraction with seasonal variations in water content, the value of K in Equation (11) is not necessarily within the range of 0.6 to 0.2, but may reach much higher values.

When gravity is the sole body force, F, in Equation (1), becomes equal to s_x, the stress in the soil. If a sufficiently prolonged drought causes shrinkage, the surface tension of the capillary water creates a capillary pressure of intensity, p_c, throughout the soil adjacent to the substructure, and the horizontal earth pressure is,

$$F' = -s_x + p_c \ldots\ldots\ldots\ldots\ldots\ldots\ldots (38a)$$

in which $s_x = (p_c + w\,y)\left(\dfrac{\mu}{1-\mu}\right)$; or,

$$F' = p_c - (p_c + w\,y)\left(\frac{\mu}{1-\mu}\right) \ldots\ldots\ldots\ldots\ldots (38b)$$

---

[12] Asst. Prof., Civ. Eng., Univ. of Washington, Seattle, Wash.

If F' falls below the magnitude of the minimum earth pressure, F_{II}, acting on a yielding wall, as determined by methods applicable to Phase II, then the soil mass behind the wall will slip until $F' = F_{\text{II}}$ as a possible minimum value. When the water-table is again raised by rainfall the tendency of the soil to expand with falling capillary pressure is limited by the fact that the soil as a whole has slipped into closer contact with the rigid structure. The ultimate pressure in this case is not the value obtained from Equation (1), but:

$$F = -s_x = -\left[(p_c + w\,y)\left(\frac{\mu}{1-\mu}\right)\right] - w\,y\left(\frac{\mu}{1-\mu}\right) + F_{\text{II}} \quad \text{(39a)}$$

or,

$$F = F_{\text{II}} - K\,(p_c + 2\,w\,y) \quad \text{(39b)}$$

The value of F, as thus determined, cannot rise above the value of the passive earth pressure, as it would then be relieved by the rupture of the soil mass. However, this latter criterion probably imposes a limitation seldom attained in Nature, as the wet-dry cycles are not generally of sufficient amplitude to make the actual capillary pressure in cohesive soils a maximum; that is, the subsoil is not commonly dried to its shrinkage limit for any appreciable depth.

Equation (39b) is introduced mainly to emphasize the distinction between temporary and permanent rigid structures. Its application in a specific case would be handicapped by the need to determine the proper value of p_c. Where circumstances warrant the procedure, this obstacle could be overcome by measuring the natural moisture content of the soil at various times of the year, and then finding the corresponding pressure from a consolidation test on an undisturbed sample.

If it is important to distinguish between a permanent, rigid, underground structure and a temporary structure (such as sheeting and bracing) in choosing a basis for design, it is also important to realize that neither method would ordinarily be chosen for the design of retaining walls, which fall within the boundaries of Phase II of the authors' "Introduction." For reasons of economy most engineers will probably continue to use the classical theories in those cases where a slight yielding of the wall is of no great consequence. Such a procedure is subject to the restriction that the wall must be actually free to slide or otherwise deflect the necessary amount. Where this rule is violated (as often happens in the case of right-angle turns in the low retaining walls on residential property), the wall will crack unless Equation (39b) has been satisfied.

It is possible, of course, to use Equation (11) for the design of flexible retaining walls, by choosing an arbitrary value for K, lower than that furnished by Equation (1). When so used, Equation (11) is no longer based upon the theory of elasticity, but becomes a statement of the equivalent fluid method. The limitations of this and other methods with respect to the position and direction of the resultant pressure make it desirable to consult the reference[4] given by the authors for cases involving Phase II.

Robert F. Legget,[13] Assoc. M. Am. Soc. C. E. (by letter).—It is refreshing to encounter so forthright a paper on so old and contentious a subject as lateral earth pressure. The background of the ten years of work which the authors mention might be thought to have provided practical evidence in support of the conclusions advanced. Fig. 5 appears to be the only such record included in the paper. Of the fourteen pages, nine are devoted to an interesting mathematical discussion of the effect of surface loads on lateral pressure, and only two to the general problem of design encountered in the vast majority of lateral earth-pressure problems. The "Theory of Design" appears to be contained in Equation (11), with the accompanying qualification, which gives the equivalent hydrostatic pressure for some arbitrary value of K, as now commonly used.

These features of the paper are mentioned since they contrast strangely with statements regarding fundamentals such as: (*a*) "* * * it has been found that the general shape of such [soil] fracture is as shown in Fig. 1. * * * [which] is independent of the type of ground * * *." (See heading, "Phase I.") And (*b*) "[The authors] have recognized that these terms are misleading and of no significance in discussing lateral pressures. * * * [and] that the road to correct determination of soil phenomena lay in such application and not in futile attempts to extend the classic formulas * * *." (See heading, "Conclusions"; the "terms" include coherent, non-coherent, internal friction, etc.). These two statements defy discussion; they prompt many questions, typical of which the following are submitted:

(1) What proof can the authors offer that the general shape of earth fracture behind a retaining wall is always curved and independent of the type of ground?

(2) Professor C. F. Jenkin[14] has conducted an investigation on the lateral pressure exerted by sand, in which theory and experience were correlated accurately. Are investigations of this caliber included in the general group of "futile atempts to extend classic formulas," and if not, how can they be considered in relation to the statement referred to in the first question?

Charles Terzaghi,[15] M. Am. Soc. C. E. (by letter).—In their paper the authors reject the application of the classical earth-pressure theories to the computation of the pressure of earth on the timbering of cuts. They also propose the application of the formula of Boussinesq to the computation of the lateral pressure due to surcharges.

During the past few years the classical earth-pressure theories have been superseded by much broader concepts, involving the elimination of the traditional assumptions of hydrostatic pressure distribution and of plane surfaces of sliding. As a consequence, most of the contradictions between theory and experience have disappeared. This "general wedge theory" explains both the high location of the center of the pressure on the timbering of cuts and the concentration of the pressures in the vicinity of the supports of flexible members. The only requirement for the successful application of the general wedge theory consists in almost full mobilization of the shearing resistance of the soil along the potential surface of sliding.

[14] "The Pressure on Retaining Walls," by C. F. Jenkin, *Minutes of Proceedings*, Inst. C. E., Vol. 234, 1932, pp. 103–223.

[15] Dr. Ing.; Visiting Lecturer, Harvard Univ., Cambridge, Mass.

In the earth-pressure tests on clean sand, reported by the writer[16] in 1934, it was found that the minimum lateral pressure developed before the wall yielded, exceeded one-fifth of the yield required for inducing a slip in the back-fill. No minimum pressure is conceivable unless the shearing resistance of the back-fill is mobilized. Hence, the fundamental requirement of the general wedge theory was satisfied long before a noticeable slip in the back-fill occurred. For the same reason one is entitled to expect that the shearing resistance of the banks on both sides of a cut through fairly dense, sandy soil can be almost fully mobilized, although the banks are still far from failing along a visible shearing surface. In such a case the application of the general wedge theory would also be justified. Quite recently this conclusion was confirmed by the results of reliable measurements made by the Siemens Bau-union in Berlin, Germany, in a cut through sand and fine gravel. On the other hand, the lateral pressure of a plastic clay on the timbering of a cut will undoubtedly be greater than the minimum pressure computed by means of the general wedge theory. For dealing with cases of this type, the authors recommend the theory of elasticity. In order to accept their suggestion, the investigator would need to know: (*a*) How to determine the value of the required soil constants by experiment; (*b*) how to compute the lateral pressure from the soil constants; and (*c*) how the results thus obtained compare with experience. No answer to these vital questions can be found in the paper. Hence, it would be premature to discuss the practical value of the suggestion.

The proposed application of Boussinesq's formulas to the computation of the lateral pressure, due to surcharges, is so tempting that the writer succumbed to this temptation twenty years ago, at the time when he started to invade his present field of research.[17] In the reference the authors can even find their Fig. 3 and the pertinent computations. However, the writer never recommended his theory for practical application because he realized at the very outset that the actual pressure values can either be much smaller or considerably greater than the theoretical ones, depending on the conditions of lateral support for the surcharged bank of earth. Thus, for instance, if the surcharge consists of a mass of earth rising at a slope from the crest of a retaining wall, the lateral pressures computed by means of Boussinesq's formulas were found to be far in excess of those which were measured by Audé and many others. On the other hand, if one applies the theory to the computation of the lateral pressure produced by concentrated surcharges whose weight is small compared to that of the "sliding wedge," the real values are approximately twice as high as the theoretical ones. It may suffice to call attention to the results of pertinent experimental investigations by M. G. Spangler,[18] Assoc. M. Am. Soc. C. E., and to the interpretation of the test results by R. D. Mindlin,[19] Jun. Am. Soc. C.E

[16] "Large Retaining Wall Tests," by Charles Terzaghi, *Engineering News-Record*, February 1, 1934.

[17] "Die Erddruckerscheinungen in örtlich beanspruchten Schüttungen," von Karl Terzaghi, *Öst. Wochenschrift für den öff. Baudienst*, 1919.

[18] "Earth Pressures on a Retaining Wall Due to a Concentrated Surface Load," by M. G. Spangler, *Proceedings*, First International Conference on Soil Mechanics, Vol. I, Cambridge, Mass., 1936, p. 200.

In 1929, E. Gerber published the results of direct measurements of the lateral pressure produced by circular and rectangular surcharges resting on the surface of a back-fill with a depth of 80 cm.[20] The measurements were made by means of very sensitive pressure cells. The writer suggests that the authors should check their theory against Mr. Gerber's test results, but he is afraid that the outcome will be rather disappointing.

The lateral surcharge pressure as computed by means of Boussinesq's formulas can be intolerably far from the truth, therefore, and the error can either be positive or negative, depending on the degree of rigidity of the lateral support and on the ratio between the weight of the surcharge and that of the "sliding wedge." On account of the difficulties connected with pertinent theoretical investigations, the subject still offers a promising field for experimental research. It would be particularly useful to measure the influence of the weight of spoil-banks and of other surcharges on the pressure in the struts of cuts at different depths below the surface.

If results of actual measurements and observations in the field are available, it is to be hoped that the authors will include them in the closing discussion.

Jacob Feld,[21] M. Am. Soc. C. E. (by letter).—A careful analysis of this paper fails to disclose very much new material or reasonably reliable methods for the determination of lateral earth or concrete pressures. It is sincerely hoped that any attempted use of the formulas or recommendations announced by the authors will be made only after a careful study of the limitations on such results. These limitations are stated in the paper, but not in such manner as to warn, sufficiently, the reader who may attempt to apply the results to future design problems.

In the "Introduction," three "phases" of the analysis of lateral pressures are enumerated, the first two dealing with lateral pressures of unfractured and fractured banks, the third being a study of the effect of surface loading. The third case should be discussed as an additional loading to each of the first two and also the possibility that such addition to the first case, unfractured bank without surcharge, will bring it into the second class. In general, if a wall, whether part of a retaining wall, bin, sheathing, or concrete form, has no elastic, plastic, or displacement motion, no pressure can be measured. If the motion is purely an elastic strain, the corresponding elastic strain in the earth can be measured by the elastic theory if the moduli of elasticity of wall and earth are fairly similar.

In the discussion of Phase I, the assumption that there are no fractured surfaces (both internal and external) is equivalent to an assumption that the internal stresses in the earth are of such nature that at no point is the tensile strength greater than the elastic limit in tension. The total distortion, elastic and displacement, must not exceed the strain at the point of elastic limit in tension. In an elastic make-up of elastic members, the less rigid will take less than its share of the load, as determined from static computation. However, as stated in the paper, the experimental work of Professor Terzaghi indicates that extremely minute displacement, far less than the smallest deformation of any economically designed sheathing or retaining wall, will result in a reduction of the measured pressure to amounts indicated by the classic earth-pressure theories; and this case is Phase II, as stated by the authors in the "Introduction."

[19] "Pressure Distribution on Retaining Walls" (Discussion), by R. D. Mindlin, *Proceedings*, International Conference on Soil Mechanics, Vol. III, Cambridge, Mass., 1936, p. 155.

[20] "Untersuchungen über die Druckverteilung in örtliche belastetem Sand," von E. Gerber; pub. Doctor's Thesis, Zürich, Switzerland, 1929.

[21] Cons. Engr., New York, N. Y.

The typical section of a fracture surface, Fig. 1, has been found by several previous writers on the subject, notably E. G. Haines[22] and H. G. Moulton,[23] Members, Am. Soc. C. E. This type of fracture is usual in slides.

In suggesting the assumption of different characteristics for soil pressure computations for members in the same sheeting and bracing unit, the authors should explain that the requirements of statics must not be forgotten. The total load on the wales can only come from the sheeting, and the total load on the braces or ties can only come from the wales. However, in computing reactions, the effect of continuity as well as the deformation of supports should be considered. The total load in all the braces or ties cannot be more or less than the total load on the sheeting.

In the discussion of the "Theory of Design—Sheeting and Bracing," it should be emphasized that Equation (1) applies only when the elastic modulus for tension as well as compression is not exceeded, and the strain and stress relationship is linear. In the design of retaining walls, the magnitude of the lateral pressure is relatively less important than its direction and the location of the point of application; these last two items are not considered in the paper.

The typical distribution of lateral pressures against a vertical face due to a surface load as shown in Fig. 2 is a fiction. No such distribution has ever been found; nor can any material be imagined in which the maximum effect is found at the top of the wall. The discontinuity of the earth surface must be considered even in the case where elastic equations may be used. Experimental results on this problem have been published by M. G. Spangler,[24] Assoc. M. Am. Soc. C. E.

A complete paper on the use and limitations of elastic theories on the determination of earth pressures was published by the late J. H. Griffith,[25] M. Am. Soc. C. E.

The limitations to the use of Equations (23) to (27),[26] evaluating lateral pressure due to various types of loading, are given as follows: "The lateral pressures, as given by Equations (23) to (27), are assumed to be distributed along rigid supports yielding no more than the elastic material which it supports." If any case of retaining wall, bin, or sheeting, can be found to comply with that limitation, the equations and tables are of value.

The theory developed for concrete pressures is not in agreement with the results of the experimental works by F. R. Shunk[27] and by E. B. Smith.[28] As the authors state (see heading, "Concrete Pressures"), pressures were obtained by translating extensometer readings based on an assumed distribution of pressure from sheeting panel to stud and wales and, in turn, to tie-rod. If the effect of continuity of studs and wales on reactions is not considered, errors in the assumed pressures will result.

For those who may be interested in a further study of the elastic theories as applied to earth pressures, reference should be made to the reports of the Special Committee of the Society to Codify Present Practice on the Bearing Value of Soils for Foundations.[29]

With the limitations included in the requirement of elasticity taken into consideration, the authors' paper is a general solution of problem. The principal objection to its applicability is the non-existence of earth materials which may be classified as elastic.

M. G. SPANGLER,[30] ASSOC. M. AM. SOC. C. E. (by letter).—Although retaining walls and allied types of construction are among the oldest and simplest kinds of structures with which engineers are concerned, there are many phenomena, related to the overturning and translating forces which retaining walls must be built to withstand, that are only dimly understood. It is to the credit of the Engineering Profession that its members are continually seeking further knowledge in regard to these phenomena, as is attested by the very extensive bibliography of this subject which is to be found in the literature. This paper is a valuable contribution to retaining wall literature and is especially noteworthy in that the authors have discarded the classical wedge theories and have based their argument upon the fundamental laws of the theory of elasticity, an approach with which the writer is wholly in sympathy.

The authors very properly divide their subject into three fundamental phases: (I) Lateral pressures when the wall is rigid enough to prevent fracture of the back-fill mass; (II) lateral pressures when the wall yields enough to permit fracture planes within the back-fill; and (III) lateral pressures induced upon the wall by surface loading. This discussion will be confined mainly to the last of these phases.

In 1936, rather extensive experiments were reported by the writer[31] in which the lateral pressures on retaining walls caused by the application of concentrated loads on the surface of the back-fill were measured. Typical results of these experiments are shown in Fig. 9. Fig. 9(*a*) shows the results of some similar experiments[32] performed at Erdgenössichen Technischen Hochschule at Zurich, Switzerland, in 1929 which are in substantial agreement with those conducted at Ames, Iowa.

This experimental evidence confirms the applicability of the Boussinesq type of equation to the qualitative distribution of pressure on a retaining wall due to a concentrated load (such as a truck wheel) acting on the surface of the back-fill. Quantitatively, however, the experimental pressures were much greater than those indicated by the Boussinesq theory when the strain-interrupting effect of an interposed retaining wall is ignored, and the authors' assumption that this effect can be neglected without serious error is not confirmed. The average pressures measured in the experiments were about 2.1 times as large as the Boussinesq pressures calculated with Poisson's ratio = 0.5 when a wheel load was placed 1.5 ft from the wall and this factor ranged to about 1.7 with the load 3.0 ft from the wall. These greater pressures resulted from the fact

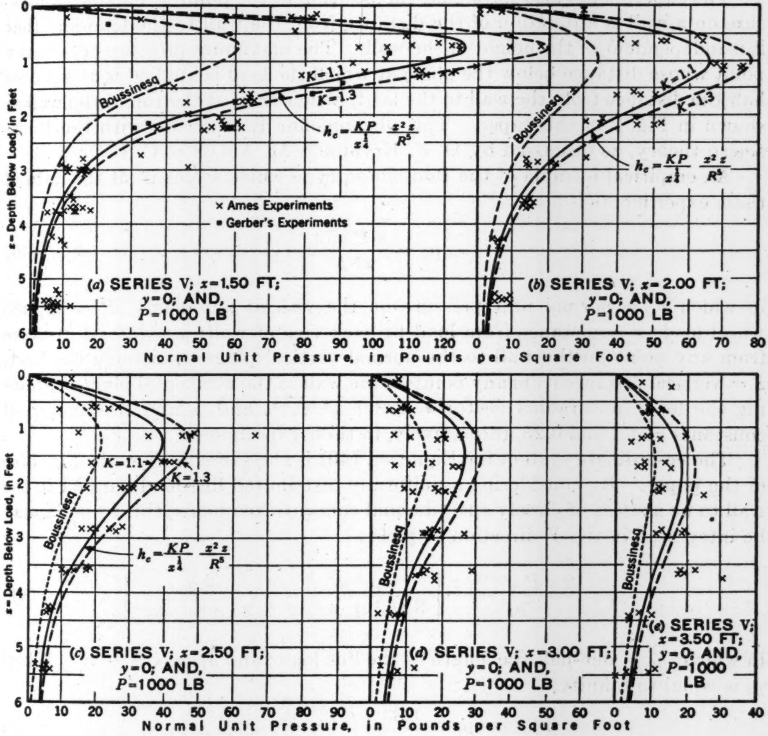

FIG. 9

---

[32] "Untersuchungen über die Druckverteilung im örtlich belasteten Sand," by Emil Gerber, Diss. a-g., gebr., Leemann, Zurich, 1929.

that the relatively rigid retaining wall suddenly interrupted the lateral strains in the gravel back-fill mass at the plane of the back face of the wall and caused an accumulation of stress over and above that which would have existed at this same plane if the wall had not been present and the gravel mass had been indefinite in extent. Furthermore, this accumulation of stress was greater when the load was nearer the wall, because the lateral strains at this plane were greater for this load position, and their interruption caused a relatively greater effect.

The experiments also show that the position of the point of maximum pressure on a wall is a function of the distance from the wall to the load and that it is independent of the height of the wall. The maximum pressure occurs at a point whose distance below the plane at which the load is applied is about one-half the distance from the wall to the load, rather than at the top of the wall as shown in Fig. 2 of the paper. This phenomenon is in accord with the Boussinesq theory, as discussed by D. P. Krynine,[33] M. Am. Soc. C. E.

An empirical formula of the Boussinesq type which seems to fit the data of these experiments is:

$$p_w = \frac{\kappa P x^2 z}{x^n \rho^5} \dotfill (40)$$

in which p_w = normal unit pressure on the wall at any point; P = applied wheel load; x = distance from load to back face of wall; y = lateral distance from any point on the wall to the normal vertical plane containing the load; z = vertical distance from any point on the wall to the horizontal plane containing the load; ρ = radius vector = $\sqrt{x^2 + y^2 + z^2}$; and, κ and n = empirical constants = 1.1 and 0.25, respectively, in these experiments.

The co-ordinate system for Equation (40) is the same as given in Fig. 3(*a*) of the paper. By considering a uniformly distributed line load parallel to the wall to be a series of closely spaced equal concentrated loads, this formula may be integrated in the Y-direction to yield:

$$p_l = \frac{2\,\kappa\, P\, x^{(2-n)}\, z}{\rho_1^4} \left[\frac{\rho_1^2\, y_0}{3\,(\rho_1^2 + y_0^2)^{1\cdot 5}} + \frac{2\, y_0}{3\sqrt{\rho_1^2 + y_0^2}} \right] \dotfill (41)$$

in which: y_0 = one-half the length of the line load; and $\rho_1 = \sqrt{x^2 + z^2}$. When y_0 is equal to infinity,

$$p_l = \frac{1.33\, \kappa\, P\, x^{2-n}\, z}{\rho_1^4} \dotfill (42)$$

In one of the experiments, a uniformly distributed line load was applied 2 ft back of, and parallel to, the retaining wall. The lateral pressures measured on the back face of the wall at a vertical element opposite the mid-point of the load are shown in Fig. 10, together with the pressures indicated by Equations (41) and (42), and by the Boussinesq theory. The close agreement between the measured values of pressure and those calculated by the integrated empirical equation proves the validity of the principle of superposition and the premise that a line load acts as a series of closely spaced concentrated loads.

---

[33] Discussion of Paper No. *J–1*, by D. P. Krynine ("The Distribution of Normal Pressure on a Retaining Wall Due to a Concentrated Surface Load," by M. G. Spangler, Vol. 1, pp. 200–207), *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., Graduate School of Eng., Harvard Univ., Cambridge, Mass., 1936, Vol. 3, pp. 159–160.

No experiments have been conducted as yet with area loads applied at the back-fill surface. In the meantime, with the line load experience as a background, it seems tenable to treat an area load as a series of parallel line loads. However, the integration of Equation (41) or (42) in the X-direction is a difficult process and has not yet been accomplished; but, by dividing an area load into a series of parallel strip loads about 1 ft wide, the pressure on a wall can be determined by arithmetical summation without an unreasonable amount of labor. It is the writer's opinion that strip elements 1 ft wide will be small enough to yield results of sufficient accuracy when dealing with stress transmission through materials having the degree of heterogeneity which most retaining wall back-fills possess.

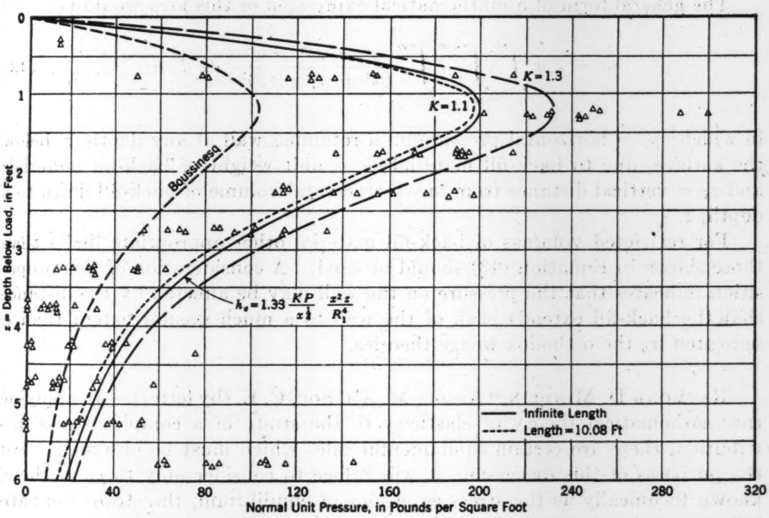

FIG. 10.—SERIES III; LINE LOAD PARALLEL TO WALL, $x = 2.00$ FEET AND $P = 1\,000$ POUNDS PER LINEAR FOOT

Furthermore, the fact of heterogeneity of back-fill materials raises the question of the feasibility of introducing Poisson's ratio into any lateral pressure formulas, whether empirical or rational, because of the difficulty of determining suitable values of this constant. An impracticable number of field determinations of the ratio would be required for a specific back-fill to obtain a suitable average value for use in formulas. Rather, the effect of Poisson's ratio should be included in the empirical disposable κ in Equations (40), (41), and (42), and working values of this factor should be determined by extensive experiments on various kinds of back-fills and retaining walls. The experiments mentioned herein are fairly adequate for the one kind of back-fill and a light wall, but they need to be duplicated for many other combinations of back-fills and walls.

Finally, the writer wishes to close this discussion by suggesting that a new approach to the problem of retaining wall pressures due to earth back-fill might be made in the light of the remarkable qualitative resemblance between the measured pressures due to surface loads and those calculated by the classical Boussinesq equations for stress distribution in an elastic solid. In such an hypothesis, the weight of each small increment of back-fill material might be considered to be a concentrated load which would transmit a horizontal pressure to a retaining wall through the mass of fill material lying below the increment. The sum of the horizontal pressures due to all such increments of volume above any point on a retaining wall would be the pressure on the wall at that point.

The general form of a mathematical expression of this idea would be:

$$p_z = \kappa\, w \int_0^z \int_{-\infty}^{+\infty} \int_0^{\infty} \frac{z_i\, x^{(2-n)}}{(x^2 + y^2 + z_i^2)^{2 \cdot 5}}\, dx\, dy\, dz_i \quad \ldots\ldots\ldots (43)$$

in which: p_z = horizontal pressure on a retaining wall at any depth, z, below the surface, due to back-fill material; w = unit weight of back-fill material; and z_i = vertical distance from any incremental volume of back-fill down to a depth, z.

For restricted volumes of back-fill material other appropriate limits than those shown in Equation (43) should be used. A consideration of this proposition indicates that the pressure on the wall may be affected by the distance that the back-fill extends back of the wall to a much greater extent than is indicated by the orthodox wedge theories.

RAYMOND D. MINDLIN,[34] ASSOC. M. AM. SOC. C. E. (by letter).—In applying the mathematical theory of elasticity to the study of a complex stress distribution, there are certain fundamental rules which must be observed. For the purposes of this discussion, it will suffice to consider only three of these, known technically as the stress equations of equilibrium, the strain compatibility conditions, and the boundary conditions.

The equilibrium equations represent a set of laws which control the variation of stress from point to point in the solid in such a manner as to assure the existence of a state of equilibrium between each element of the solid and the surrounding elements.

Proper observance of the compatibility conditions assures geometric continuity of the deformed solid; that is, there will be no overlapping or separation of adjacent elements if these conditions are fulfilled.

The foregoing requirements are satisfied by infinite numbers of stress distributions. Which of these distributions will actually exist in the solid depends upon the shape of the body and the forces acting on it. The "boundary conditions" constitute a formulation of the latter conditions.

A simple example will illustrate these principles. Consider a beam that is subjected, successively, to the following actions: (1) Simply supported at its ends and carrying a concentrated load at its center; (2) fixed at its ends and carrying a load uniformly distributed over its length; and (3) constrained along a certain part so that it will remain rigidly undeformed while loads are applied to other parts. It is clear that each of these cases will result in a different stress distribution but all of them may satisfy the equilibrium and compatibility conditions. No designer could properly maintain that the stresses calculated for one case would apply to the others.

An analogous situation to the foregoing presents itself in the paper. The authors have taken several well-known solutions of the elasticity equations, valid for the particular boundaries and boundary conditions for which they were intended, and have applied them to very different boundaries and boundary conditions. The stresses, of course, still satisfy the equilibrium and compatibility conditions but, without more supporting evidence than is given in the paper, they can no more be said to describe the states of stress that exist in the problems presented than do the stresses in a uniformly loaded, fixed-end beam coincide with the stresses in a simply supported beam carrying a concentrated load. In fact, certain key solutions are noted subsequently which indicate that the conclusions of the authors may involve under-estimates as great as 100%, and almost unlimited over-estimates.

Gravitational Loading.—Turning to the equations offered in the paper, it is observed that the authors state that "for an elastic solid subject to its own weight alone, the total lateral pressure at any depth, y, below the surface is given by [Equation (1)]." In the light of the foregoing discussion, it is necessary to investigate the boundary conditions to which such a pressure might conform.

First, a body acted upon by its own weight alone would move with gravitational acceleration and would be entirely unstressed. If the body is to remain stationary, it must be supported. One method of support is by means of forces applied to the surface of the body. This implies specification of the shape of the solid—that is, a description of its boundaries. Furthermore, it implies specification of the conditions of stress or displacement on these boundaries. A sphere resting on a horizontal plane support will not have the same stress distribution as a cube held in a similar manner; and a sphere resting on three point supports will have still a different stress distribution.

In writing Equation (1), the authors perhaps had in mind the semi-infinite solid. In order to study the validity of the equation in this case, it is necessary first to describe, completely, the state of stress of which Equation (1) is only a part.

The semi-infinite solid is one having as its upper boundary a horizontal plane of indefinite extent, the solid itself extending indefinitely downward from the plane. Consider a system of rectangular co-ordinates, x, y, z, oriented so that the $X-Y$-plane coincides with the plane boundary, and the Z-axis penetrates vertically downward into the solid. Let σ_x, σ_y, σ_z, τ_{yz}, τ_{zx}, τ_{xy} represent the six components of stress at any point in the solid, in accordance with an accepted notation.[35] Then, the complete specification of stress, partially represented by Equation (1), is:

---

[35] "Theory of Elasticity," by S. Timoshenko, N. Y., 1934.

$$\sigma_x = -\, w\, z \frac{\mu}{1 - \mu} \quad \text{(44a)}$$

$$\sigma_y = -\, w\, z \frac{\mu}{1 - \mu} \quad \text{(44b)}$$

$$\sigma_z = -\, w\, z \quad \text{(44c)}$$

and,

$$\tau_{yz} = \tau_{zx} = \tau_{xy} = 0 \quad \text{(44d)}$$

The strains, ϵ_x, ϵ_y, ϵ_z, γ_{yz}, γ_{zx}, γ_{xy}, corresponding with the six components of stress, are found by using Hooke's law for an isotropic material:

$$\epsilon_x = \frac{1}{E}\left[\sigma_x - \mu(\sigma_y + \sigma_z)\right] \quad \text{(45a)}$$

$$\epsilon_y = \frac{1}{E}\left[\sigma_y - \mu(\sigma_z + \sigma_x)\right] \quad \text{(45b)}$$

$$\epsilon_z = \frac{1}{E}\left[\sigma_z - \mu(\sigma_x + \sigma_y)\right] \quad \text{(45c)}$$

$$\gamma_{yz} = \frac{\tau_{yz}}{G} \quad \text{(45d)}$$

$$\gamma_{zx} = \frac{\tau_{zx}}{G} \quad \text{(45e)}$$

and,

$$\gamma_{xy} = \frac{\tau_{xy}}{G} \quad \text{(45f)}$$

Substituting in Equations (45) the values of the stress components given in Equations (44), it is found that,

$$\epsilon_x = \epsilon_y = 0 \quad \text{(46)}$$

Hence the lateral pressure given by Equations (44) (and Equation (1)) results from the assumption that there is no lateral displacement or deformation of any vertical plane in the solid. In a semi-infinite solid this may be interpreted as setting up a boundary condition. Since many other types of lateral restraint may be postulated, it is apparent that Equation (1) cannot be accepted as general even for the semi-infinite solid.

The state of stress in a large earth mass, approximating the specifications of a semi-infinite solid, and subjected to gravitational loading only, cannot be determined definitely from the theory of elasticity alone. The stress situation that exists in a particular earth mass depends upon the past history of the body. Experiments, interpreted by means of elasticity theory, might give some indications, but not theory alone.

Poisson's Ratio and Hooke's Law.—Following Equation (1) the authors make certain statements concerning Poisson's ratio which are not quite accurate. They state, "if it were greater than 0.5, the material would not resist distortion; and if it were less than − 1, it would not resist compression." These limits are determined from a consideration of the principle of conservation of energy.

Concerning the properties of a material for which Poisson's ratio is 0.5, two possibilities exist: (1) If the shear modulus is zero; and (2) if the shear modulus is not zero. In the first case the medium resembles a perfect liquid; in the second case, the material is an incompressible solid. The authors further state that Equations (2), (3), and (4) are equations of equilibrium. These equations represent a partial statement of Hooke's law for an isotropic material.

Lateral Pressures Due to Surface Loads.—Under this heading the authors discuss the Boussinesq solution and certain subsidiary solutions obtained from Boussinesq's problem by integration. All these solutions satisfy the boundary conditions for the semi-infinite solid, and were intended by their originators to apply only to such a solid. The authors, however, propose to use these results to describe the pressure distributions against retaining walls and sheeting.

The presence of an obstructing wall in the material completely changes the boundary conditions and, therefore, will change the state of stress in the solid. To visualize the causes of the change, consider, in the semi-infinite solid, a section, $A\ B\ C$ (Fig. 11), which is a vertical plane before the application of the surface load. Then, apply a load on the surface at some distance from the trace, $A\ C$, of the vertical plane in the surface. Plane $A\ B\ C$ then deforms into a curved surface and there will be certain stresses acting on this surface. Suppose, now, that the material to the left of $A\ B\ C$ is removed. To retain the original state of stress in the material on the right side of $A\ B\ C$, the deformation of $A\ B\ C$ must be maintained by applying to this surface, from the left, the same distribution of stress that was originally supplied by the material removed. If either the stress or the strain on $A\ B\ C$ is changed, the Boussinesq distribution will no longer be maintained in the remaining material. If a wall is placed against $A\ B\ C$ instead of the stresses applied from the left, the deformation of Surface $A\ B\ C$ will be changed and, hence, the stress distribution both in the entire body and against $A\ B\ C$ will also change. The magnitude of these changes will depend upon the shape and elastic properties of the wall and its surface roughness. By the principle of superposition, the same conclusions will be reached if the wall were present from the beginning and the surface load applied later. That these considerations are not pure speculation is verified by the remarkable experiments of M. G. Spangler,[11]

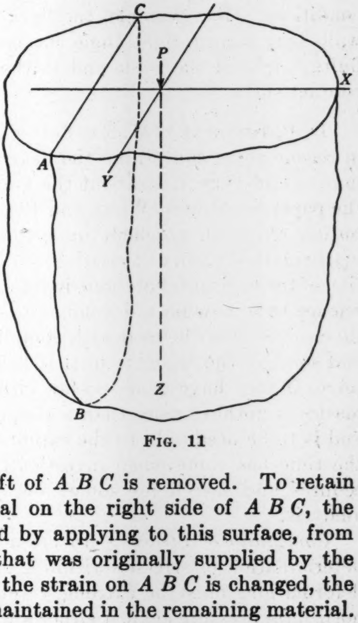

FIG. 11

Assoc. M. Am. Soc. C. E., which show that the actual pressures are about double those predicted by the authors.

It must be concluded, therefore, that Equations (12) to (27) do not apply to the problem under consideration. A sound study of the problem should include consideration of the interaction between the wall and the hypothetical elastic soil. A general solution of the problem involves difficulties which have not yet been overcome by students of elasticity. However, limiting cases have been treated and these throw light on the situation. For example, if the wall is relatively rigid in comparison with the soil, it may be assumed, as a first approximation, that the wall is perfectly rigid. Solutions obtained on this assumption [10] show rather good agreement with Professor Spangler's experiments. They do not, however, agree with the stress distribution depicted by the authors in Fig. 2. In fact, the authors' own proposals do not agree with Fig. 2.

"Rigid wall" solutions are also available for a variety of other boundary conditions. For example, the back face of the wall may be inclined, or two walls may form a right-angle corner. Consideration can also be given to the finite height of the walls and to the roughness or smoothness of some of the contact surfaces.

D. P. KRYNINE,[36] M. AM. SOC. C. E. (by letter).—Much has been written in recent years concerning the determination of the vertical pressure in earth masses and very little about the horizontal pressure. This is the reason why the paper by Messrs. White and Paaswell is especially welcome. Their contribution offers an excellent opportunity to clarify the question of when the mathematical theory of elasticity may or may not be applied to the determination of the horizontal pressure in soils. Analytical procedures applicable to that science have now been developed to such an extent that average engineers feel themselves overwhelmed with complicated operations and page-long formulas; and some of the students in that field stop to ponder, and begin to ask themselves if they have gone too far with all this mathematics. After all, mathematics is nothing more than a simple engineering tool like a shovel or a pick and is to be used only to the extent necessary to serve its purpose. Perhaps, the time has come when investigators must simplify existing analytical procedures and search for some new and more direct methods of engineering analysis.

Continuity of Strains.—In order to apply the theory of elasticity to the determination of stresses within a body the strains must be continuous, and deformations must be extremely small. With these conditions in mind, the horizontal pressure against either a wall or a sheeting and bracing can be determined by using the theory of elasticity, but only if these particular structures or parts of structures do not yield under the action of that horizontal pressure. If they yield, the upper surface of the back-fill will settle, and there will be no continuity of strains.

Professor Terzaghi[37] has shown that when a retaining wall begins to move, the horizontal pressure decreases and reaches a minimum (which is practically the value given by the Coulomb formula) at the moment of failure. Hence, the horizontal pressure determined by using elastic formulas must be greater than the pressure computed using Coulomb's formula. A rather rigid retaining wall, completely prevented from yielding, may fail, whereas a rather weak wall, but one that is permitted to move, may stand the strain quite satisfactorily. It may be concluded from this apparently paradoxical statement, that structures acted upon by the horizontal pressure should not be fixed against a slight lateral movement; and this restricts the possible field of application of the theory of elasticity to such structures.

[37] "A Fundamental Fallacy in Earth Pressure Computation," by Charles Terzaghi, M. Am. Soc. C. E., *Journal*, Boston Soc. C. E., Vol. 23, No. 2, April, 1936.

The pressure distribution shown in Fig. 2 never occurs. This statement can also be proved by the principle of continuity of strains. In fact, strains in a sand mass can be continuous only if isolated particles are so pressed against each other that no mutual displacement of grains is possible, and if only elastic deformations occur. Mass acquires this condition when isolated particles are entirely restrained against movement. It is evident that particles at the surface of a sand mass are not so restrained. They can be moved freely, and, therefore, do not form a body in the sense used in mechanics. They are merely loose grains which can produce no horizontal pressure. Experiments by M. G. Spangler,[38] Assoc. M. Am. Soc. C. E., have revealed zero horizontal pressure at the top of a sand-gravel mass, which is quite consistent from the theoretical point of view.

When the back-fill is composed of clay (which may be considered as an elastically isotropic body) the situation is somewhat different. The horizontal pressure computed according to elastic theories is first negative (directed from the wall), the computations progressing from the surface of the ground, A, down to a certain point, B; then it is positive (toward the wall) down to a certain point, C; and negative again from Point C downward, as shown in Fig. 12 which is a simple free-hand sketch. Pressure measurements would show positive pressure along Distance $B\ C$ only; and the appearance of a fissure at the top of the wall along Distance $A\ B$ may be expected. In any event, Fig. 12 is not the same as Fig. 2, even in the case of a clay back-fill.

Poisson's Ratio.—Elastic formulas for determining stresses contain Poisson's ratio, μ, or its reciprocal, $m = \frac{1}{\mu}$. As used in elastic formulas, m is a constant. The authors propose using two different values of Poisson's ratio—the smallest for the sheeting and the highest for the braces. In other words, it has been suggested to design the sheeting for one kind of soil, and the bracing for another, both kinds of soil being completely hypothetical. Such a suggestion would be entirely acceptable if it were certain that Poisson's ratio maintains a constant value during the process of loading; but there is no such certainty since experimental data to support such a statement are completely lacking.

Investigators in soil mechanics agree that the modulus of elasticity of a soil is not a constant value; it increases with the depth. It is only logical, then, to think that Poisson's ratio also changes its value with the depth since, due to compression by the over-burden and to the formation of a "disturbed zone" under the loaded part of the earth surface, physical properties of an earth mass change with the depth. This is still another argument against the use of elastic formulas in the given case.

[38] "The Distribution of Normal Pressure on a Retaining Wall Due to a Concentrated Surface Load," by M. G. Spangler, *Proceedings*, International Conference on Soil Mechanics and Foundation Eng., Vol. 1 (1936), pp. 200–207; also, *Bulletin No. 140*, Iowa Engineering Experiment Station (1938), Iowa State Coll., Ames, Iowa.

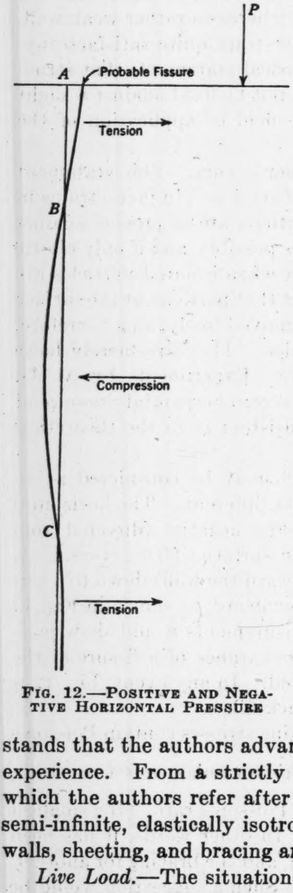

FIG. 12.—POSITIVE AND NEGATIVE HORIZONTAL PRESSURE

In general, the use of the term "Poisson's ratio" as applied to soils is questionable. The term may be applied to an elastically isotropic "continuum" in which there are no pores or voids; it represents the ratio of lateral strain to the axial strain in such a continuum. In a porous material the lateral deformation that appears as the result of an axial stress, changes the shape of individual grains and gradually fills the voids with matter, while the surface of the mass settles. In this case, the term "Poisson's ratio" loses its original meaning. German engineers prefer the use of a conventional term, *Querzahl*, or "transverse number," instead of the classical term, "Poisson's ratio."

Horizontal Pressure Due to the Weight of the Earth Mass.—The authors suggest that Equation (11) be used to compute the horizontal pressure due to the weight of the earth; and, that the coefficient, K, in this equation, "may receive a maximum value of 0.6 and a minimum value of 0.2. A rational method of designing sheeting and bracing would be to use the maximum value of K for the more rigid members of the supporting system and a much smaller one for the flexible sheeting." The writer understands that the authors advance this rule as an empirical one based on practical experience. From a strictly theoretical viewpoint, however, Equation (1), to which the authors refer after introducing Equation (11), was developed for a semi-infinite, elastically isotropic, mass and cannot be applied when retaining walls, sheeting, and bracing are included in that semi-infinite mass.

Live Load.—The situation involving a live load acting at the boundary of the back-fill, at a certain distance from the wall, is different from that corresponding to earth pressure. The live load is applied when the wall has already moved and is in a rather steady position. Due to repeated applications of the live load the earth mass acquires elasticity. Furthermore, the weight of a live load is generally small in comparison with that of the back-fill. Thus it may be assumed that in the case of a live load elastic formulas hold. Obviously, this is true only so far as stresses at a certain depth are concerned since the horizontal pressure at the ground surface equals zero, as previously stated.

Spherical Co-ordinates.—Equation (12) representing the lateral pressure, F, is given in spherical co-ordinates, α, β and ρ. This is an excellent way to describe the stressed condition in the case of a single concentrated force, P, acting vertically at the boundary of the mass, since the entire problem is perfectly symmetrical about the vertical axis, $O\,Z$ (Fig. 3(a)); but, in the case of two or more loads acting at the boundary, there are difficulties in using spherical co-ordinates since the results given by Equation (12), for each of the given loads, cannot be added vectorially. To clarify this statement, Fig. 13 has been prepared. The maximum horizontal pressure caused by each of the two loads, P_1 and P_2, acting at the ground surface, is confined in the vertical plane passing through the vertical line of action of the respective load and the given point, O. The two horizontal pressures intersect as shown in the plan (Fig. 13(a)) and are to be added geometrically.

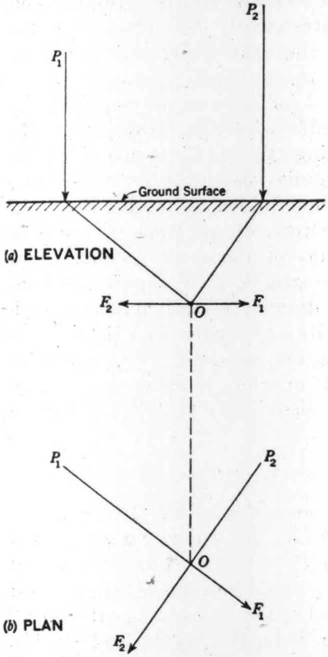

FIG. 13.—HORIZONTAL PRESSURE FROM TWO CONCENTRATED LOADS

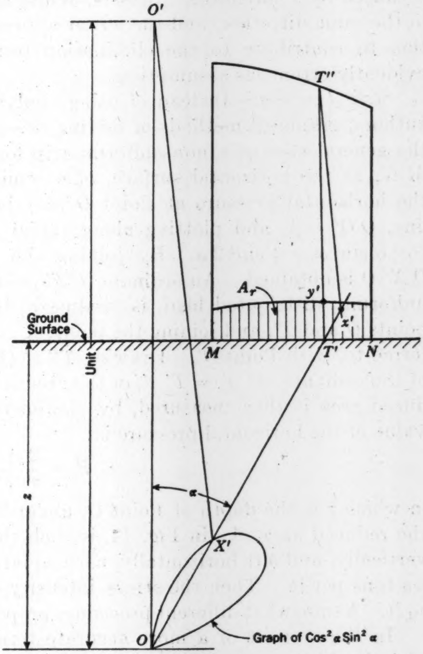

FIG. 14.—HORIZONTAL PRESSURE UNDER A STRIP LOAD

Rectangular Loading.—It is to be borne in mind that Equation (14), and the text to Equation (22d), refer to the case of a rectangular loading, one of the sides of the latter being parallel to the retaining wall in question or, more accurately, to the plane normal to which the horizontal pressure in question acts (see drawing in Table 3). The authors rightly state that "the assumption of a single concentration is accurate" in the case of a rather small pier footing;

but, in the general case of a long rectangular loading, as shown in Fig. 3(*b*), this statement is no longer valid. It may be concluded from the paper that the authors themselves are of this opinion, but this fact should be emphasized. Mr. Spangler's experiments[38] destroyed the wrong assumption made by designers as to uniform distribution of pressure along the height of a wall if that pressure is caused by a surcharge. Messrs. White and Paaswell take a theoretical step in the same direction; and the writer appreciates greatly their plausible intention to contribute to the elimination from the engineering practice of an evidently erroneous assumption.

Strip Loading.—Instead of using analytical formulas as developed by the authors, graphical methods of solving this problem have been proposed.[39] In the general case of a non-uniform strip loading (Fig. 14) covering a section, $M\,N$, at the horizontal surface, of a semi-infinite elastically isotropic body, the horizontal pressure at Point O may be determined by tracing a vertical line, $O\,O' = 1$, and plotting along radial vectors, drawn from O, values of $\cos^2\alpha \sin^2\alpha = \frac{1}{4}\sin^2 2\alpha$. By joining the ends of the radii vectors, Locus $O\,X'\,O$ is obtained. An ordinate, $T'T''$, of the area, $M\,T''N$, showing the non-uniformly distributed load, is "reduced" by drawing a straight line through points O and T', and joining the point, X', of its intersection with the locus referred to, with Point O'. Drawing $T''\,x'$ (Fig. 14) parallel to $O'X'$, the value of the ordinate, $T'\,y' = T'\,x'$, of the "reduced" area, A_r, is obtained. The reduced area is then measured, by planimeter, or in some other way, and the value of the horizontal pressure is:

$$F = \frac{2}{\pi}\frac{A_r}{z}. \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (47)$$

in which z is the depth of Point O, under the ground surface. If the scale of the reduced area, A_r, in Fig. 14, is such that 1 in. represents a tons per sq ft vertically, and b ft horizontally, each square inch of that area would represent $a\,b$ tons per ft. Then the stress intensity, F, would be measured in tons per sq ft. A somewhat different procedure proposed by the writer may be also used.[40]

In the interest of a more accurate terminology, the "point load" in Fig. 4(*a*) should be termed "line load," since this is an infinitely long straight line at the ground surface loaded with $\overline{p}$ units of weight per unit of length.

Horizontal Pressure and Pressure on a Retaining Wall.—Attention should be called to the fact that Pressures F, computed according to elastic theories, are stresses within the mass itself. Using the method of images, R. D. Mindlin,[41] Jun. Am. Soc. C. E., has shown that the pressure on a retaining wall is not F, but $2\,F$.

Conclusions.—The main principle of this paper, in that it defends the application of the theory of elasticity to the determination of the horizontal pressure against sheeting and bracing, is questionable. The paper itself, however, is to be welcomed as a contribution to the field in which practically no mathematical study has been done in recent years.

David A. Molitor,[42] M. Am. Soc. C. E. (by letter).—After reviewing this paper, wherein it is recommended that the classic theories of earth pressure be discarded without supplying any adequate substitute, one wonders what method should be used in future. Actually, only the special case of lateral pressures due to single or strip-surface loads is treated. The title, therefore, is too inclusive for the subject matter presented.

The authors mention three phases of retaining wall problems, as follows:

(1) Pressures distributed along a wall sufficiently rigid or unyielding so that no fracture surfaces appear in the ground or bank;

(2) Pressures developed as a result of a fracture surface or surface of rupture caused by a slight movement of the wall; and,

(3) The distribution of pressures due to a surface loading. Phase (1) is not treated in detail; Phase (2) is the basis for Coulomb's theory, which the authors recommend be discarded; and Phase (3) is the case analyzed by an application of the Boussinesq-Hertz formulas and comprises most of the paper. The writer has never seen a case that could properly be classed as belonging under Phase (1). Even if the wall structure is perfectly rigid (which condition was more likely to exist in the days when only gravity type walls were in use) the elasticity of the foundation is always sufficient to cause a decided movement in the back-fill, not to mention the ever-occurring settlement.

No wall can be regarded as safe and enduring unless it is so designed that it will stand at least 1 yr without undergoing any serious displacement, either of overturning or sliding on the base. Under such circumstances would any designer be warranted in pursuing any other than a safe course by providing adequately for the possible maximum earth pressure? Hence, whether he likes it or not, the engineer's design problems will continue to be solved according to Coulomb, Poncelet, Scheffler, Rankine, Winkler, etc., on the basis of the prism of maximum pressure, Phase (2), and nothing better has been proposed as yet.

As for Phase (3) (which is merely a special case of surcharge superimposed on Phase (2)) the lengthy mathematical treatment in the paper is interesting but of comparatively little value until an entirely new set of empiric coefficients is determined. This is equivalent to reminding the designer that he must first conduct some elaborate test experiments prior to designing a wall.

The authors state that they hope to present the development of the pressures due to shear failure on the assumption that the failure surface is a cosine curve. Furthermore, a typical section of fracture surface is shown in Fig. 1, and it is stated that this surface is independent of the type of ground. Others have assumed the fracture surface to be of circular cross-section.

The writer contends that the surface of rupture is of hyperbolic section, and that its particular shape and location is purely a characteristic of the type of ground and its moisture content, as described in a paper[43] giving a full account of actual measurements of such failure surfaces for clay embankments as high as 65 ft, with a possible application to the earth-pressure problem.

[42] Cons. Engr., Harlingen, Tex.

[43] "The Present Status of Engineering Knowledge Respecting Masonry Construction," by David Molitor, *Journal*, Association of Eng. Societies, 1900.

In 1937 the writer presented in brief form[44] the most usable features of the many theories evolved in the past, and explained how these theories may be applied in a practical manner to retaining-wall and sheet-piling problems. To those designers who still feel that the classic earth-pressure theories are not yet doomed to oblivion, this information should prove valuable.

It is regrettable that the term "equivalent fluid pressure" has crept into modern textbooks. The term could apply only to the case of level-back fill. As most wall problems involve surcharge in some form, the designation is not fitting.

In conclusion it should be emphasized that the design of a large, reinforced retaining wall, with or without surcharged back-fill, requires more than mere textbook knowledge and should be undertaken only after considerable experience and mature judgment are acquired.

Predicated on these qualifications, the classic theories will no doubt endure for quite some time to come, or at least until something much better can be evolved. When one considers the immense number of walls and structures, designed and built during the past, with a relatively small percentage of failures traceable to poor judgment, it must be acknowledged that the classic theories have served well in practice.

Ralph W. Stewart,[45] M. Am. Soc. C. E. (by letter).—Lateral pressures on retaining walls produced by concentrated loads on the ground surface behind the walls, which is investigated by the authors, was also studied both experimentally and analytically by M. G. Spangler, Assoc. M. Am. Soc. C. E., at the Iowa Engineering Experiment Station and the results were published in April, 1938.[46] One rather important difference is noted between the authors' conception of the distribution of pressure and the findings by Professor Spangler. In Fig. 2 the lateral pressure due to a surface load which is set back some distance from the back of the wall is indicated as maximum at the top of the wall. The Iowa tests show this pressure as zero. The latter is obviously correct as a thin stratum of granular earth along the surface could not act as a strut to transmit horizontal pressure from P (in Fig. 2) to the top of the wall. If called upon to perform this duty it would fail by buckling—that is, the surface of the ground would bulge upward. As illustrated in Fig. 15, the actual pressure distribution curve, according to the numerous observations reported in Iowa, forms a bulb whose maximum ordinate is somewhat below the top of the wall, depending on how far back the load is.

[44] "Structural Engineering Problems," by David A. Molitor, The Peters Co., Detroit, Mich., 1937, Chapters 9 and 10.

[45] Engr. of Bridge and Structural Design, City of Los Angeles, Los Angeles, Calif.

[46] Iowa State College Bulletin No. 140, Ames, Iowa, 1938.

LAZARUS WHITE,[47] AND GEORGE PAASWELL,[48] MEMBERS, AM. SOC. C. E. (by letter).—In May, 1933, Hardy Cross, M. Am. Soc. C. E., addressing the New York Metropolitan Section of the Society, stated that by nature the engineer is not primarily a scientist, a mathematician, an experimental physicist nor a laboratory man. Formulas and experiments are "mechanical brains" which cannot take the place of the human brain when applied to the control of the forces of nature for the benefit of Man.

For the best description of the nature of the engineer, Professor Cross quoted from Robert Louis Stevenson's book "Records of a Family of Engineers," which records the history of Stevenson's father and grandfather, both famous engineers. For the benefit of the discussers of the writers' paper, foundation engineers are in a field where there is, in the words of Stevenson, "but a restricted use for formulas. In this sort of practice, the engineer has need of some transcendental sense. Smeaton, the pioneer, bade him obey his 'feelings'; my father, that 'power of estimating obscure forces which supplies a coefficient of its own to every rule.' The rules must be everywhere indeed; * * * everywhere bent to the impression of the trained eye and the *feelings* of the engineer." Stevenson calls attention to "the insignificance of much Engineering literature." "So far as the science can be reduced to formulas or diagrams, the [engineers] book is to the point; so far as the art depends on intimate study of the ways of nature, the author's words will too often be found vapid."

The writers believe that their observations were based upon an "intimate study of the ways of nature" and even if the formulas they attempted to advance are deficient (as they are certain to be) they should be of aid to any engineer who wishes to comprehend the processes of nature in the field discussed; and they will help to supply, to obscure forces, that "transcendental sense" which distinguishes the engineer. As Stevenson observes, he should have "a sentiment of physical laws and of the scale of nature, which shall have been strong in the beginning and progressively fortified by observation, and must be his guide in the last recourse."

It is to be hoped that genuine engineers are not as rare as Smeaton, of whom Stevenson recites this anecdote: "Duke of Argyle to Smeaton (who declined a commission), 'You can recommend some other fit person?' asked the Duke. 'No, I am sorry I cannot,' replied Smeaton. The Duke: 'What a profession with only one engineer in it. Pray, who taught you?' 'Why,' said Smeaton, 'I believe I may say I was self taught, may it please your grace.'"

The writers, instead of being self-taught like Smeaton, had the benefit of competent teachers of engineering and imbibed the classical theories of Coulomb and Rankine who were of quite a respectable age even in Smeaton's time. For quite a while the writers believed in them thoroughly. However, being brought up to check theories as against nature, constantly, their experience quite flatly indicated the classical theories, and as far back as 1908 came to observe with the late J. C. Meem, M. Am. Soc. C. E., and E. G. Haines, M. Am. Soc. C. E., that the pressures of an earth bank should be held by braces placed at the top—that the fracture of banks was conchoidal instead of plane. By a more correct observation of actual pressures, great economies in systems of bracing and sheeting were realized without a sacrifice of safety—on the contrary, with an increase of safety that should always be realized when dealing with a correct understanding of nature's working. Later, about 1915, in connection with underpinning, the Pretest method was invented which depended upon the elastic properties of earth. This was given mathematical expression by Professor Terzaghi, in the application of Boussinesq, in computing the vertical pressures beneath a footing; the plottings of such pressures in isopressure lines by experiment or calculation gives the "bulb of pressure," which affords a valuable graphic representation of the variation in vertical pressures beneath a footing, or can be applied also to pressures in a horizontal direction opposite wales or braces in a timber system; photo-elastic observation presented a strikingly visual confirmation of the "bulb of pressure."

---

[47] Pres., Spencer, White & Prentis, Inc., New York, N. Y.

[48] Secy. and Treas., Spencer & Ross, Inc., Detroit, Mich.

In his experiments on retaining walls, Professor Terzaghi demonstrated the great effect of very small movements on the lateral pressure.[16] Such effects, to the writers' minds, could only be explained properly by the elastic properties of earth.

The elastic theory was also applied successfully to a study of concrete pressures, with great economy. The writers are surprised that no discussions of this part of the paper were submitted because great sums are spent on forms which are designed with some modification of liquid pressure, or by "rule-of-thumb," with consequent crudeness or extravagance. Considerable experimentation could be done in this field as actual measurements of pressures in forms are much easier than in earth banks.

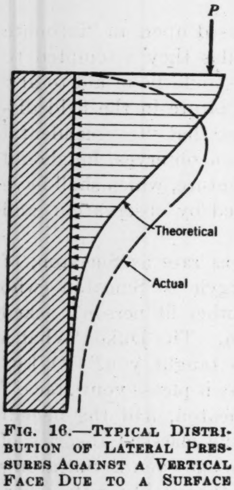

FIG. 16.—TYPICAL DISTRIBUTION OF LATERAL PRESSURES AGAINST A VERTICAL FACE DUE TO A SURFACE LOAD

An undue amount of attention was given to Fig. 2 of the paper; the effect of a free surface was ignored but a slight modification such as that in Fig. 16 would satisfy the criticism. From time to time the writers obtained measurements on braces which, in general, corroborated Fig. 16, but no favorable opportunity was afforded until the last section for the Sixth Avenue subway in New York, N. Y., was being excavated. Here a long section of cut was supported by steel wales and braces rigidly wedged to the masonry walls of the Hudson and Manhattan Railroad, affording an almost ideal opportunity to measure the actual lateral pressures. The cross-section of the cut and method of steel support in open cut is shown in Fig. 17. Where the cut was clear of buildings and adjacent underpinning, vertical steel beams were driven and directly supported by steel braces. Horizontal sheeting was used between verticals and the ground was carefully drained by ditches and sumps during excavation.

By means of the apparatus shown in Fig. 18 the pressures on the braces could be ascertained within 2 or 3 tons. The apparatus was that ordinarily used in underpinning—a hand pump, capable of exerting a pressure of 5 000 to 6 000 lb per sq in.; two 4.5-in. hydraulic jacks of about 40 tons capacity; the wooden wedges expanded against the flanges of the 10-in. H-beam and after a slight slippage gripped sufficiently to hold 10 to 20 tons for each pair; the end of the beam, when tapped with a steel hammer, while holding its load, emitted a clear ringing note like a tuning fork; when the beam was unloaded between the two pairs of wooden wedges and the wale, the note changed so that its unloaded condition could be detected before any space between beam and wale was visible to the eye. Thus the loading conditions were practically unchanged. The apparatus described is simple and accurate when a calibrated hydraulic gage is used. (In Fig. 18 note the copper tubes leading to the jacks.)

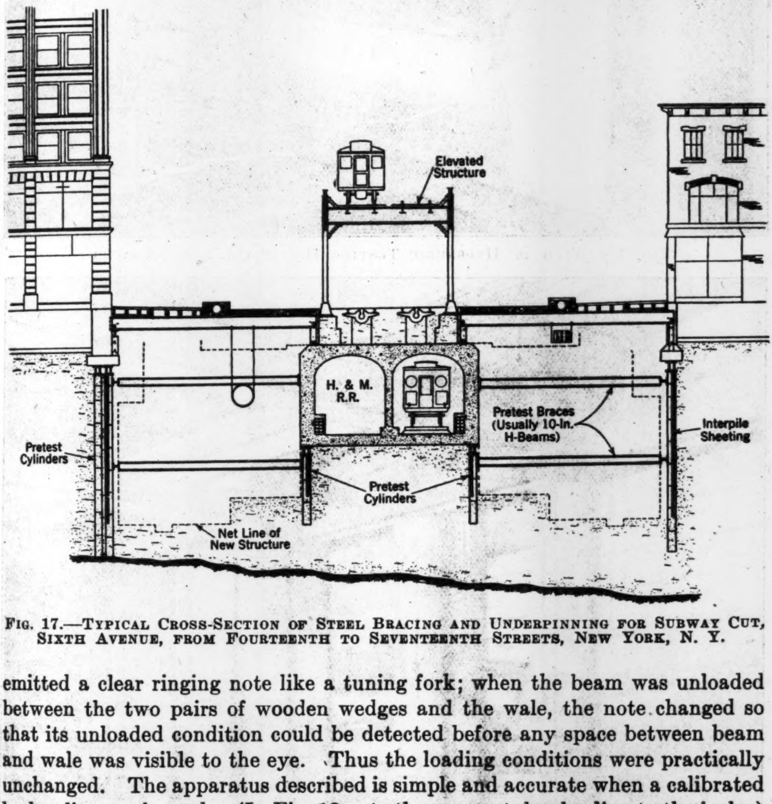

Fig. 17.—Typical Cross-Section of Steel Bracing and Underpinning for Subway Cut, Sixth Avenue, from Fourteenth to Seventeenth Streets, New York, N. Y.

For several months a trained gang of three men accumulated considerable data which were used in the designs of steel bracing, with resulting economies. It was easy to check the actual loads at any time—in no case were dangerous pressures observed—and yet the bracing (see Fig. 19) seemed light when compared to that ordinarily used; particularly the lower braces were more widely spaced, which required the use of heavier wales. The best system was to omit wales and brace the vertical beams directly. One surprising result was that despite a great variation of ground—quicksand, "bull's liver," fine to coarse sand and gravel in the natural drained ground—the pressures as mea-

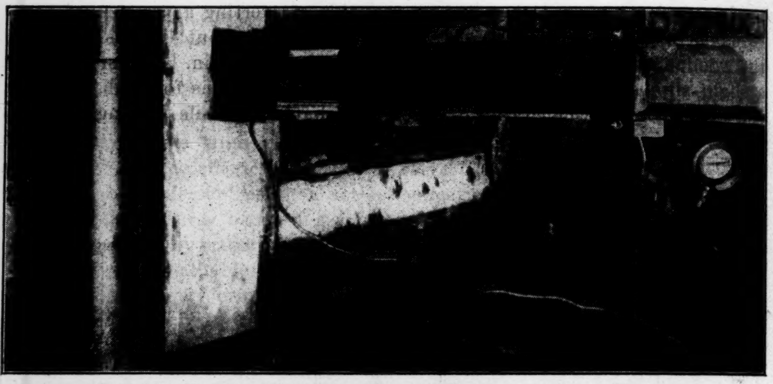

FIG. 18.—VIEW OF HYDRAULIC TESTING DEVICE FOR STEEL BRACES

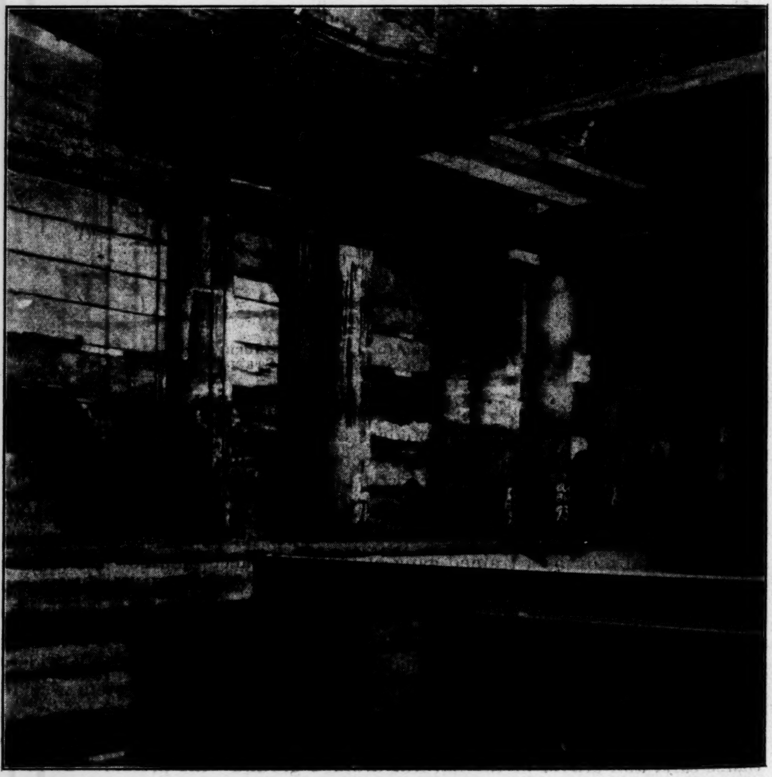

FIG. 19.—VIEW OF STEEL BRACING, UNDERPINNING AND SHEETING, SUBWAY CUT, NEW YORK, N. Y.

sured seemed to be quite uniform and not responsive to variations in strata. The results of measurements are given in Fig. 20. The curves conform in general to those of the elastic theory. Note that in one case where a new foreman neglected his drainage and allowed the bottom to become quick, the bank broke, and settlement occurred in the adjacent underpinning, with no lateral movement because of the steel bracing against the adjacent subway; yet the pressure after the break was less than the pressure before, indicating that the "elastic" pressure is greater than the "wedge" pressure. Mr. Bedrich Fruhauf computed pressures by the formulas given in the paper and found that it is necessary to make a modifying assumption to obtain values similar to those of Fig. 20. The formula assumes perfect elasticity to infinity which produces a straight-line increase of pressure with depth. This does not conform with observation, so it seems reasonable to limit the assumption to a

vertical plane a reasonable distance back. In ordinary materials (well drained) a distance equal to the depth of cut or wall would seem to be ample. Calculations on different assumptions are given in Fig. 21. The bank was divided into horizontal layers 1 ft thick, and vertical slices 20 ft, 40 ft, and 100 ft wide. Each horizontal layer was considered as a surcharge to the material below. Poisson's ratio, μ, was assumed at 0.2. Different values of μ affect the total pressure but not the form of pressure curve.

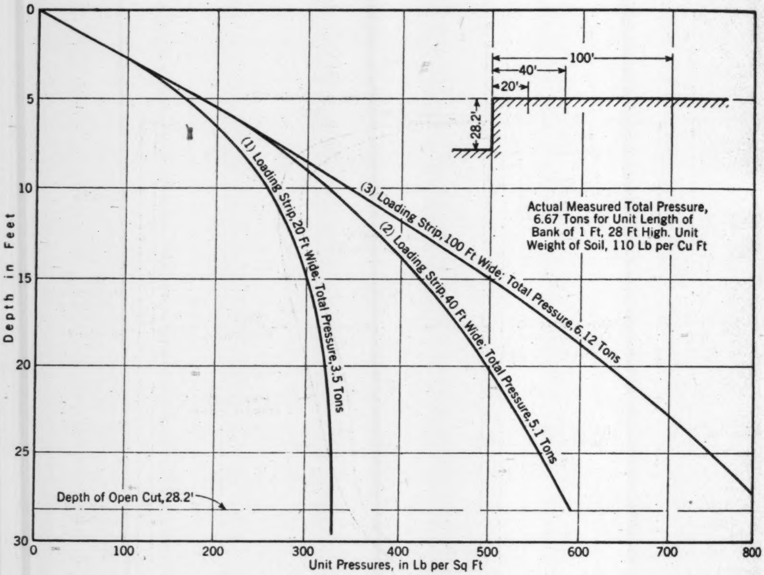

FIG. 21.—COMPUTED LATERAL EARTH PRESSURE FOR LENGTH OF BANK OF 1 FOOT, USING EQUATION (14) AND THE RECTANGULAR LOADING IN FIG. 3(*b*)

In comparing the calculated value with measured values, allowance must be made for the modifying effect of wedging the upper braces, which tends to throw the lateral load high. It will be seen that some of the curves approximate quite closely the measured results of Fig. 20 with reasonable values of μ, Poisson's ratio.

It may be objected that the writers are modifying their equations in two ways by limiting the elastic effect to a material between the sheeting and an arbitrary vertical plane and also by selecting a favorable value of μ. To this they must plead that they are applying Stevenson's "transcendental sense," or applying a coefficient of their own in estimating obscure forces.

The writers believe that their method of approach conforms to nature much more closely than others; and that, by simple and rational assumptions which they often have made, an economical and safe system of bracing can be devised. They have done this repeatedly and on a large scale without untoward results. However, this must be accompanied by good workmanship, thorough drainage, by the use of open sheeting, by thorough packing of the sheeting, and by the entire elimination of quick or boiling ground in every stage of the work.

An erroneous conception of earth and concrete pressures is given by the analogy of fluid pressures, particularly by the use of the coefficient K where earth or concrete material is considered as a fluid, with pressures reduced in accordance with the values of K. Although the total pressure by choosing a proper K may be approximately correct, this gives a totally erroneous concept of the increase of pressure with depth. The Coulomb or Rankine wedge is only a special case and does not explain, adequately, the phenomena of earth pressure; nor does it lead to proper design of supporting sheeting or bracing or retaining walls.

Although the total pressure of a bank or fill may range between fairly wide limits, its manner of application or points of application are profoundly modified by the various rigidities of the supporting members, either sheeting or bracing or retaining walls. The vertical members of a system of bracing act as a foundation, and as the cut deepens they are subjected to increasing loads. These loads may cause serious distortion of the entire bracing system if they do not provide an adequate foundation. The writers do not claim any final word on the subject of lateral earth or concrete pressures, but merely wish to set their successors on the correct path.

However, they must close with some words of warning: It seems simple to build a box and fill it with earth and measure the resultant pressures; and this has been done repeatedly with results varying in value with the experience or "transcendental sense" of the observer. Compare the material deposited in a box, however, with nature's materials. It is disturbed, drained, and consolidated; it has a concrete or wooden floor, a rigid foundation; the material is restrained on the sides and bottom; in practice the wall or sheeting has a toe hold, it is braced arbitrarily, and has flexible sheeting and wales. It may be saturated at times (if not thoroughly drained) and subject to hydrostatic pressure added to dry earth pressures; the foundation may become quick and yielding due to imperfect drainage; and, the wall may move seasonably. The materials and wall are often subject to vibrations from railroad and traffic, compacting the material which follows up every slight movement of wall. It thus happens that retaining walls have the worst record of failures of any engineering structures, and such failures may occur long after they are built; but close observation would probably have shown progressive movements. A retaining wall cannot be designed arbitrarily from any formula but requires that "transcendental sense" necessary to the engineer in the design of all structures, which cannot be safely "picked" from handbooks.

It seems strange that a century and a half after Coulomb, engineers are only on the threshold of knowledge in the field of lateral earth pressures. Still more difficult of analysis are the pressure effects of breaks in materials like silt and soft clays which are difficult to drain and which break in wide and deep spherical masses, creating tremendous disturbances.

The writers wish to comment on the concrete pressures given in Fig. 5. A very rigid form with steel wales and bolts was filled with vibrated concrete of low slump; the bolts were evenly spread and about 5 ft apart; the form was filled to the height of about 40 ft; in the bolts whose tension was measured by a strain gage, a maximum tension was built up corresponding to about 750 lb per sq ft. This tension was retained long after the concrete had set and until the nuts were slackened. Certainly this demonstrated the fallacy of considering concrete as a fluid.

A THEORY OF SILT TRANSPORTATION

BY W. M. GRIFFITH,[1] ESQ.

WITH DISCUSSION BY MESSRS. JOE W. JOHNSON, G. W. HOWARD, HARRY F. BLANEY, E. W. LANE, O. A. FARIS, J. E. CHRISTIANSEN, SAMUEL SHULITS, GERALD LACEY, GLENN W. HOLMES, HUNTER ROUSE, S. G. BAUER, C. C. INGLIS, AND W. M. GRIFFITH.

SYNOPSIS

A theory of silt transportation is outlined in this paper, and equilibrium equations are presented which it is claimed are applicable to channels of all sizes and shapes, provided the silt load and the bed consist of "loose granular material," and provided certain hydraulic conditions are satisfied. The equations are of special value in problems relating to river-control works and tidal river outfalls; for example, they can be used to estimate the change in bed level that will result from widening or "tightening" a river section, or to determine whether a proposed dredge cut can be expected to maintain itself.

The study of silt transportation originated in the efforts of irrigation engineers to design artificial channels that would carry the heavily silt-laden waters of the rivers which supplied them, without silting their beds or scouring their banks. Attention is still mainly directed to this aspect of silt transportation, but the principles are actually of wider application. The same problem, in general, is involved in river-control works and in the improvement of the outfall of tidal rivers for navigation and drainage purposes.

THE GENERAL THEORY

In a paper[2] published in 1927, the writer advanced a theory of silt transportation, in which it was suggested that changes which occur in the cross-section of rivers and canals after artificial alteration of the existing conditions can be mathematically calculated by reference to a single elementary law. The theory was based on two assumptions: (1) That the transportation of silt is effected by the reaction of vertical eddies or the vertical resultant of other

---

NOTE.—Published in May, 1938, *Proceedings*.

[1] Cambridge, England.

[2] "A Theory of Silt and Scour," by W. M. Griffith, *Minutes of Proceedings*, Inst. C. E., Vol. 223 (1927).

eddies; and (2) that the level of the bed at every point in a cross-section is governed by the law of silt transportation.

This theory is applicable to any channel section in which: (1) The bed of the channel is composed of loose granular material incapable of substantial shear resistance; (2) the silt load is of the same material; and (3) the flow is turbulent and follows the boundary surfaces.

The elementary law of silt transportation may be briefly stated thus: In a given cross-section of a stream, the condition for equilibrium at any point in the bed is given by the relation,

$$v = c\,d^n \qquad (1)$$

in which v is the mean velocity in the vertical through the point in question; d is the depth at that point; c is a coefficient varying with the amount of silt load carried; and n is an exponent the numerical value of which must slightly exceed 0.5.

Consider a naturally formed river section in which flow is taking place under the conditions stated (see Fig. 1). This may be segmental, semi-elliptical, parabolic, or of similar shape, but for simplicity's sake it will be designated parabolic. It is claimed that from Chezy's basic equations of flow for unerodible perimeters, the average velocities in the vertical planes through the points, A, B, C, etc., across the section will vary as the square root of the depths at those points; that is, as $d_1^{0.5}$, $d_2^{0.5}$, $d_3^{0.5}$, etc.[3] Now, if the silt load is uniformly distributed across the section, the velocities required for equilibrium under the law of silt transportation will vary as d^n. Hence, if the true value of n is 0.5, all points in the cross-section will be in equilibrium whatever its shape may be—deep and narrow, or broad and shallow; but if the value of n is either greater or less than 0.5, there can be only one value of d at which equilibrium is attained.

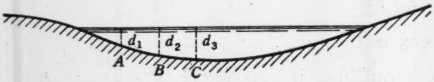

FIG. 1

Assume this value to occur at the mean depth of the parabolic section. Then, if the true value of n is less than 0.5, in the deep center the actual velocity will exceed that required for equilibrium by Equation (1) and in the shallow sides it will be less. The section, therefore, will tend to scour in the center and shoal near the sides and thus become deeper and narrower. If the true value of n is greater than 0.5, the reverse will be the case and the channel will tend to flatten out into a broad, shallow cross-section.

As channel sections carrying heavy silt loads do tend to flatten out, it is argued that the value of n must be greater than 0.5. However, observation shows that parabolic sections flowing under the conditions stated do have some stability; hence, the value of $(n - 0.5)$ cannot be great.

A parabolic section can be in equilibrium at all points if the silt load varies across the section directly as $\frac{v}{d^n}$, or, in other words, as $\frac{1}{d^{n-0.5}}$, since $\frac{v}{d^{0.5}}$ is constant across the section by the hydraulic law. If the value of $(n - 0.5)$ is small, this required variation in silt load across the section will not be great. By depositing silt where the actual velocity is in deficit, and picking it up by scour where the velocity is in excess, the stream will tend to adjust its silt load at different points across the section to that distribution which will give stability.

---

[3] *Minutes of Proceedings*, Inst. C. E., Vol. 223 (1927), pp. 245, 246, and 279.

Cross-eddies redistributing the silt charge will tend to upset this state of equilibrium. Hence, a channel of parabolic section, with a bed of sand and a silt charge of the same material, can have no permanent stability, and its temporary stability will depend on such absence of cross-eddies as can be gained by the channel being straight and of uniform section.

If a channel with an erodible bed is provided with smooth, unerodible sides, it can achieve stability only by flowing at one depth—that is, by forming a level bed across the section—and it invariably does so. A common example is found in the beds of irrigation canals which have to carry silt loads of sand in their upper reaches. An example will also be found in the beds of tidal rivers, either near their outfall, where the sides are lined, or at the outfall, where unerodible sides are provided by training walls.

Beyond the training walls, where no unerodible sides exist, any channel forming in the sand bed must of necessity have a parabolic section, but such channels have only a temporary stability. This stability is increased to some extent by the deposit, at the sides, of colloids, which produce a material having some shear resistance.

DEVELOPMENT OF EQUATIONS

It follows from Equation (1) that,

$$V_m = f\,c\,(d_m)^n \qquad (2)$$

in which V_m is the mean velocity of the whole cross-section and d_m is the mean depth; f is a factor depending on the shape of the cross-section. $f = \frac{V_m}{v_m}$, in which v_m is the mean velocity in the vertical through the point where the depth is d_m.

The value of f can be mathematically determined for any known type of cross-section. Thus, for a rectangular cross-section, $f = 1.0$; for a triangular cross-section, $f = 1.13$; and for a natural river cross-section,[4] its value will differ little from 1.1.

If B = the width at water surface, and Q = the discharge, then, $Q = V_m\,B\,d_m$, or,

$$V_m = \frac{Q}{B\,d_m} \qquad (3)$$

Substituting in Equation (3) the value of V_m from Equation (2),

$$\frac{Q}{f\,c} = B\,(d_m)^{n+1} \qquad (4)$$

Consider any two cross-sections of a channel, sufficiently close to each other to insure the value of Q and c to be unchanged. Let d_{m1} and d_{m2} be the mean depth of these two sections, and B_1 and B_2 their surface widths. Since for the same type of cross-section the value of f is constant, and since $\frac{Q}{f\,c}$ is constant, from Equation (4),

---

[4] "A Theory of Silt and Scour," by W. M. Griffith, *Minutes of Proceedings*, Inst. C. E., Vol. 223 (1927), p. 253.

$$B_1\,(d_{m1})^{n+1} = B_2\,(d_{m2})^{n+1}$$

Therefore,

$$\frac{B_1}{B_2} = \left(\frac{d_{m2}}{d_{m1}}\right)^{n+1} \qquad (5)$$

or,

$$d_{m2} = d_{m1}\left(\frac{B_1}{B_2}\right)^{\frac{1}{n+1}} \qquad (6a)$$

Equation (6*a*) gives the values of changes in depths resulting from widening or tightening a river section when the types of the two cross-sections are similar.

Where the type of cross-section is changed, as for example from the parabolic to a rectangular type, as will occur at the site of a weir or bridge, the value of f will not be constant and Equation (6*a*) becomes,

$$d_{m2} = d_{m1}\left(\frac{f_1\,B_1}{f_2\,B_2}\right)^{\frac{1}{n+1}} \qquad (6b)$$

in which f_1 and f_2 are the shape factors of the cross-sections at d_1 and d_2, respectively.

For a change from a natural river cross-section to a rectangular cross-section, the value of $\frac{f_1}{f_2}$ will approximate to 1.1.

In the fundamental equation (Equation (1)) since c varies with the silt load, it can be expressed in terms thereof. Let c_1 be the silt load of loose granular material (excluding colloids), expressed in terms of parts per 10 000 by weight, that is carried in the vertical above a point on the bed of a channel. Then,

$$c_1 = z\,\frac{v}{d^n} \qquad (7)$$

in which z is a new coefficient and,

$$c_1 = z\,c \qquad (8)$$

The term, "loose granular material," is intended to include shingle or sand down to an order of fineness of about $\frac{1}{500}$ in. in diameter, but it does not include light materials carried in suspension by all eddies—such as clay, organic matter, and sand of an extreme order of fineness. All such light materials, for the purpose of this paper, are classed as colloids because they do not fulfill the primary condition that their transportation is dependent on the vertical eddies alone.

If the value of $\frac{v}{d^n}$ is sufficiently high to transport the loose granular material, the colloids will remain in suspension and cannot be deposited, so they do not affect the bed. For this reason the beds of channels in which loose granular material is being transported will not be found to contain colloids in any quantity. Some quantity of fine sand, which by comparison with the loose granular material is of a second order of smallness, will be found within the interstices of the latter, where it finds shelter. However, the quantity will not exceed the natural volume of the voids, and so will not affect the bulk of the bed material, or, consequently, the level of the bed at any point.

If the values of n and z are known, Equations (1), (2), (5), (6*a*), and (7) offer a mathematical solution to many river and canal problems.

The Value of n.—The value of n can be determined by a graphic analysis of the values of V_m and d_m of a series of channels of different depths, all carrying the same quantity of silt load and all having beds in equilibrium under this silt load.

This method was adopted by R. G. Kennedy in his classical paper.[5] However, Kennedy analyzed the data in terms of the maximum depth of the section, instead of the mean depth, because he made no fundamental assumption, and his analysis was purely for the purpose of discovering an empirical relationship applicable to a number of irrigation canals, all having more or less the same type of cross-section. A number of other observers followed the same process, but although the channels studied by any one observer may have been of a single type of cross-section, they were not necessarily similar to those studied by Kennedy or by any of the others.

Kennedy's value for the exponent, n, was 0.64, and other observers have arrived at values[6] varying from 0.44 to 0.727. As the beds of all the channels studied appear to have been of sand, such a large variation in the value of the exponent is illogical, because model experiments indicate that normal differences in the sizes of grains in the wetted perimeter do not materially affect the coefficient of roughness, or the conditions of flow.

Of course, if boulders are present in a river bed, they form definite obstructions to flow, of a different order of size, and the hydraulic conditions are altered. Their effect can be observed, for example, in time of flood, when the water surface will be found to be irregular, having the appearance of a series of waves, and indicating flow of a different order of turbulence. Hence, for shingle and boulder beds, a different value for n might be anticipated.

In his paper of 1927,[7] the writer found the value of n in Equation (2) to be equal to 0.59, approximately, by a graphic analysis of Kennedy's data in terms of d_m instead of d. In examples given in that paper, relating to sites on the Jumna and Ganges Rivers, which have beds of boulders and shingle, the writer assumed a value for n of 0.64. In 1930, a similar analysis of both Kennedy's data and the Madras[8] data showed that a value of n of 0.57 fitted both sets of data with reasonable accuracy.[9] Further investigation has led to the conclusion that this value may be accepted as approximately correct for beds of medium to fine sand. With regard to beds of shingle and boulders, a rough analysis of some flood discharges of the Jumna River gave a value of 0.65.

The Value of z.—Having now obtained a provisional value for n, the value of z in Equation (7) can be found from observations of silt content, velocities, and depths.

[6] "Stable Channels in Erodible Material," by E. W. Lane, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 127.

[7] *Minutes of Proceedings*, Inst. C. E., Vol. 223 (1927), p. 279.

[8] "Critical Velocity Observations," Public Works Dept., Irrigation Branch, Madras, India, 1912.

[9] *Minutes of Proceedings*, Inst. C. E., Vol. 229 (1927), pp. 321, and 322.

An examination of the very complete collection of silt analysis and hydraulic data in a valuable paper by Harry F. Blaney, M. Am. Soc. C. E., and the late Samuel Fortier, M. Am. Soc. C. E.,[10] together with certain silt-sample analyses from the waters of the Wash at the tidal outfall of the River Great Ouse (which have been made under the writer's supervision), has led to the conclusion that a value of z of 7.5 in Equation (7) fits both sets of data with reasonable accuracy. This value is, therefore, provisionally recommended for graded sand (colloids being omitted); however, further investigation is required to determine how this value is affected by the size of the sand carried, and how far, if at all, it is affected by colloids if present in large quantities.

Substituting these values for n and z, Equations (1), (2), (6a), (6b), and (7) become, respectively,

$$v = c\, d^{0.57} \qquad (9)$$

$$V_m = f\, c\, (d_m)^{0.57} \qquad (10)$$

For similar types of section,

$$d_{m2} = d_{m1} \left(\frac{B_1}{B_2}\right)^{0.637} \qquad (11)$$

For dissimilar types of section,

$$d_{m2} = d_{m1} \left(\frac{f_1\, B_1}{f_2\, B_2}\right)^{0.637} \qquad (12)$$

and,

$$c_1 = \frac{7.5\, v}{d^{0.57}} \qquad (13)$$

CHECK OF EQUATIONS WITH OBSERVATIONAL DATA

Canals.—The examination of silt analyses just referred to is given in Tables 1 to 4. Table 1 shows an analysis of the silt load in a cross-section of the Central Main Canal (Imperial Valley Canals, California). Columns (1), (2), (3), (4), and (6) are taken from Table 21 of the paper by Messrs. Fortier and Blaney,[10] and Columns (5), (7), (8), and (9) have been computed by the writer.

Column (7), Table 1, gives the arithmetic means of the four silt-load observations at each station. However, owing to the relatively high concentration of silt load near the bottom of the channel at certain stations, this arithmetic mean does not always give an accurate value of the true mean silt load. Hence, the observations at each station were plotted, as in Fig. 2, and the mean silt loads determined graphically from these plots are given in Column (8). It will be seen that where the relative value of the bottom silt load is high, the value of the arithmetic mean is much in excess of the mean value found graphically.

In Column (9), the values of $\frac{7.5\, v}{d^{0.57}}$ are entered, and a comparison of Columns (8) and (9) shows that a close agreement exists between the actual silt load and the load calculated from the hydraulic conditions by Equation (13).

Table 2 gives similar data for the Dahlia Canal, the observed data being taken from Table 22 of the Fortier and Blaney paper.[10] In this case, owing to the fact that only three silt samples were taken in the total depth, the graphic method of arriving at the mean silt content is not possible. Where the bottom values are relatively high, the arithmetic mean must be in excess of the true mean, which would account for the fact that the higher values in Column (7) are in excess of those in Column (8).

Table 3 gives similar figures for other canals and for the Colorado River. In these cases the values of the bottom samples are not relatively high and the silt contents given by the arithmetic mean (Column (7)) would be more nearly correct. The very close agreement between the entries in Columns (6), covering a fairly wide range of depths and velocities, is somewhat remarkable.

The velocities in Table 4 are surface velocities. Observation indicates that the relationship between the surface velocity, v_s, and the mean velocity in a vertical plane, v, agrees roughly with Bazin's relationship between the maximum surface velocity and the mean velocity of the entire section; that is, the ratio of v_s to v is on the order of 1.28 to 1. On the other hand, the silt contents given

in Table 4 include colloids, because apparatus for the separation of the colloid portion was not available.

Owing to the tendency of salt water to deposit colloids, the colloid content in these samples was not great. However, it must be greater on the ebb tide, or outflow, than on the flood tide, or inflow. It will be less, the farther out from Point *A* (Fig. 3), the observation point is and will be small at Site *C*.

Fig. 4 shows the variation in silt content at Site *B* on a neap tide, during the period from low water to high water, throughout which the velocities and depths were changing. (These observations were taken from a boat at anchor and the length of anchor chain permitted of some change of position under the varying flow, so the samples were not all taken at exactly the same spot.)

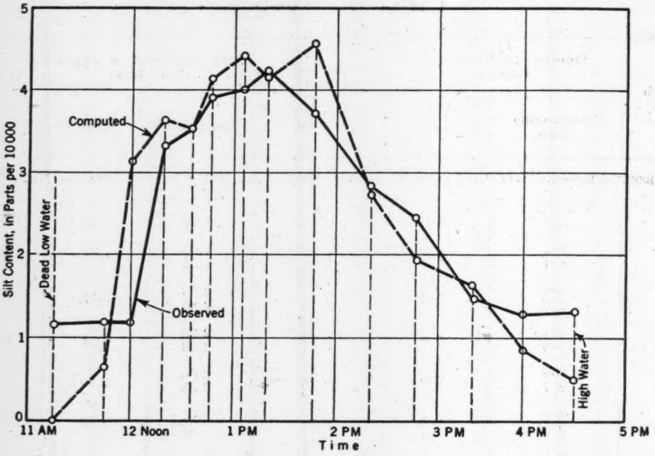

FIG. 4.—SILT CONTENT AT SITE *B*; AVERAGE NEAP TIDE, LOW WATER TO HIGH WATER

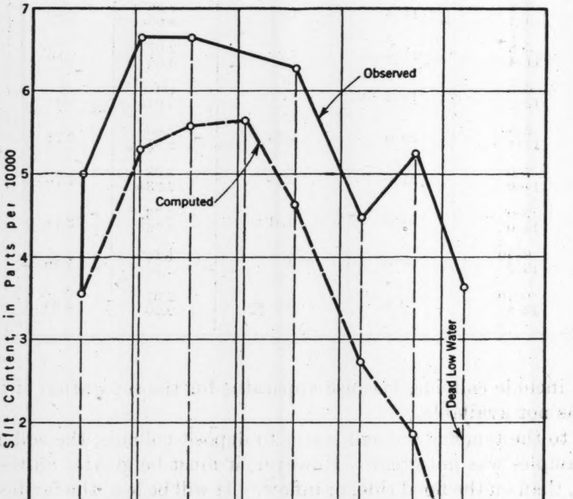

FIG. 5.—SILT CONTENT AT SITE *B*; LOW SPRING TIDE, EBB

The curve of values of $\frac{7.5\, v_s}{d^{0.57}}$ is also plotted. It will be noticed that the two curves show a close agreement, but that there is a time lag of about 30 min between them, as might be expected. Details of these observations are given in Table 4(*a*).

Fig. 5 gives similar curves at the same site for an ebb tide. Again, the curves are similar, but in this case the observed silt content is continuously in excess of that computed by formula. This fact is presumably due to the increased quantity of colloids on the ebb flow. The values are tabulated in Table 4(*b*).

Fig. 6 and Table 4(*c*) give observations taken for part of the ebb flow at Site *A*. In this case, despite the fact that owing to the ebb flow the colloid content would be relatively great, the computed curve lies above the curve of observed silt content. In explanation it may be stated that at Site *A* conditions are changing so rapidly that the actual silt content lags behind that computed from the hydraulic conditions.

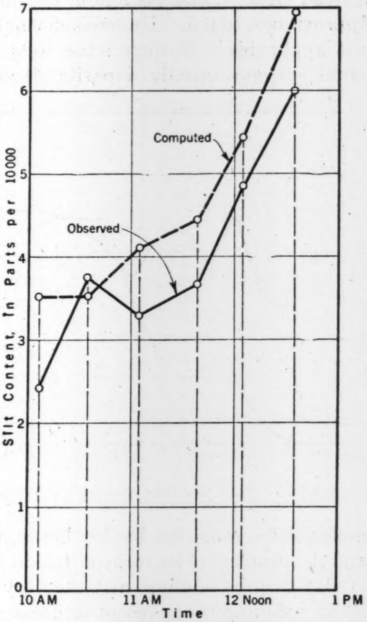

FIG. 6.—SILT CONTENT AT SITE *A*; LOW SPRING TIDE, EBB (PART ONLY)

Fig. 7 and Table 4(*d*) give similar curves for a neap tide, from low water to high water at Site *C*. At that site, velocities are lower and depths greater, and there is a considerable increase in wave action. This wave action, in the shallow waters of the Wash, creates a turbulence sufficient to maintain a considerable silt content even when the velocity is zero. Under such conditions, the hydraulic factors have little effect on the silt content.

The turbulence created by wave action depends on the height of the waves, which, in turn, depends on the area of the water surface. This area is greater at high tide than at low tide on account of the area of sand banks then exposed, and explains why the silt content is greater at high water than at low.

APPLICATION OF THEORY

Canals.—In canal systems required to carry quantities of graded sand together with colloids as silt loads, the conditions named apply in the upper reaches. In the lower reaches much of this graded sand may have passed out of the system and a different condition may pertain.

The difference between these two conditions may be seen from the difference in the type of cross-section. In the upper reaches the section will be nearly rectangular, the bed being approximately level except close to the sides, where the reduction of velocity resulting from the horizontal eddies from the sides will cause a slight rise of bed. In the lower reaches, if the silt load consists of light material only, the bed will be curved.

In turbulent flow within stream-lined boundaries the eddies in general are a function of R, the hydraulic radius. However, the vertical eddies (or the vertical resultants of the eddies) are a function[11] of d_m. Therefore, if the silt content is largely colloidal, the silt transporting power will be a function of R^n instead of $(d_m)^n$, and the lighter the material the more closely will the value of n approximate to 0.5. Under such conditions the theory outlined in this paper is not applicable. However, the light material found in the lower reaches of canal systems usually deposits slowly, and when excavated forms a useful material for repairing banks; hence, it is often more beneficial than harmful, and the problem of its transportation is usually not a serious one. The presence of clay insures binding, and the very fineness of the sand appears to give it a shear resistance not present in coarser sand.

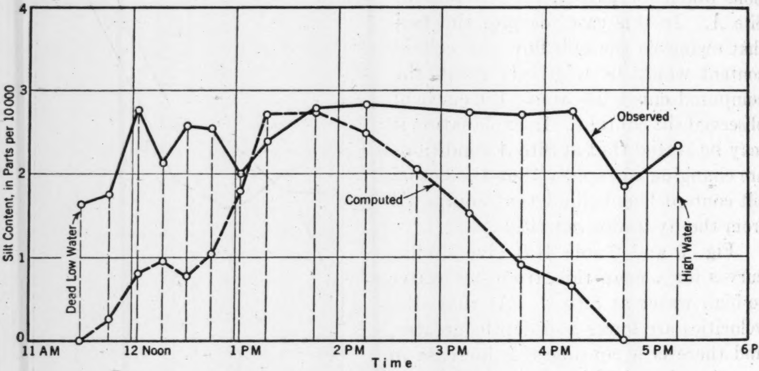

FIG. 7.—SILT CONTENT AT SITE *C*; AVERAGE NEAP TIDE, LOW WATER TO HIGH WATER

Where the present theory is applicable, the condition required to insure that the full silt load of the parent stream will be carried by the offtake canal is that the value of $\frac{V_m}{(d_m)^n}\left(\text{or, for ordinary silt, } \frac{V_m}{(d_m)^{0.57}}\right)$ of this offtake canal shall not be less than the value of this ratio in the parent channel. The question of whether the inflow to the canal actually has a higher or a lower silt concentration than the parent channel itself, depends on the hydraulic conditions at the offtake. By scientific design of the offtake, it is possible to reduce the silt load greatly in the offtake channel.

Again, where the silt charge is heavy, and the surface slope limited, it is desirable to provide a canal section having the maximum silt-carrying capacity. Such a section is secured if the ratio $\frac{V_m}{(d_m)^n}$ has a maximum value, and the width and depth of bed giving the maximum value for this ratio can be found by plotting its values for different types of sections.[12]

---

[11] *Minutes of Proceedings*, Inst. C. E., Vol. 223 (1927), pp. 276 and 277.

In the foregoing it has been assumed that the most suitable side slopes for the channel have been predetermined. In practice, the correct value for the side slopes is found by experience, and will depend on such factors as: (1) Vegetation at the sides; (2) amount of colloids in the silt content; (3) angle of repose of the natural material; (4) velocity; and (5) ruling radius of curvature.

It is not claimed that this or any theory of silt transportation can solve all silt difficulties of canals. The writer's experience indicates that most cases of silt trouble are most easily and cheaply dealt with by reducing the silt content at the head of the canal by a more scientific design of the intake works. The writer considers that Kennedy's original theory, by concentrating so much attention on the detail of the channel design, has diverted attention from the study of the silt distribution at the offtake, where the true solution to the silting problem may usually be found. The Imperial Valley Canals appear to be a case in point.

River Control Works and Tidal River Outfalls.—As already stated, Equations (6*a*), (6*b*), or Equations (11) or (12), provide a means of determining changes in bed level which may be anticipated from widening or "tightening" existing river sections. An example is afforded by the three cross-sections of the Hundred Foot River given in Fig. 8. Approximately $\frac{5}{8}$ mile of this river, between Cross-Section No. 108 and Cross-Section No. 114, was widened ill advisedly. Cross-Section No. 111 is a typical cross-section of this widening. The elevation of the water surface varies, but the mean water level is about as shown in Fig. 8. The necessary hydraulic data for testing Equation (11) are given in Table 5.

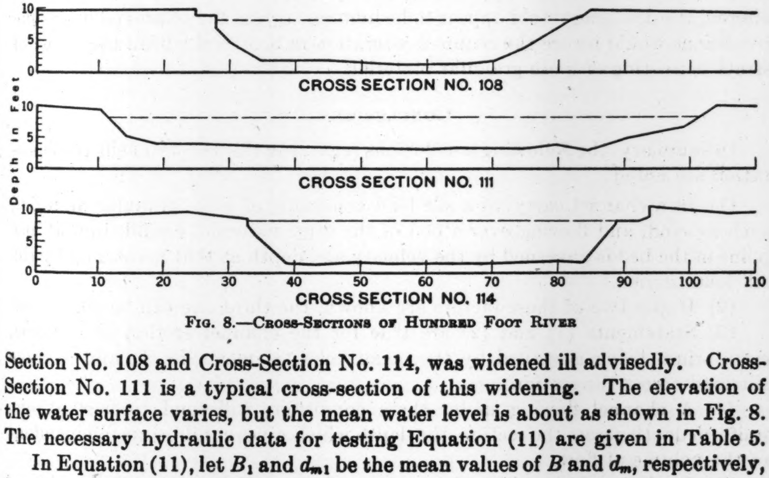

FIG. 8.—CROSS-SECTIONS OF HUNDRED FOOT RIVER

In Equation (11), let B_1 and d_{m1} be the mean values of B and d_m, respectively, for the unwidened sections, and let B_2 be the width of the widened section. Then, $d_{m2} = d_{m1}\left(\frac{B_1}{B_2}\right)^{0.637} = 5.725\left(\frac{54.9}{89.8}\right)^{0.637} = 4.18$ ft, the calculated value of the mean depth of the widened section. This value compares with an observed mean depth of 4.08 ft, a difference of less than 3 per cent.

---

[12] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), pp. 184 and 185.

As a general example of the use of this theory in tidal river outfall problems, mention again may be made of the River Great Ouse. In recent years the tidal section of that river has silted sufficiently to threaten the safety of the low-lying fen country which it drains. Several types of remedial measures have been proposed, but opinions have differed as to their respective merits.

TABLE 5.—HYDRAULIC DATA FOR HUNDRED FOOT RIVER

Cross-Section No.	B, in feet	Area, in square feet	d_m, in feet	Remarks
108	53.8	304	5.65	Unwidened sections
114	56.0	325	5.80	Unwidened sections
...	54.9	...	5.725	Mean value of unwidened section
iii	89.8	366	4.08	Widened section

By the use of the present theory, a study of the hydraulic conditions of the non-tidal and tidal sections of the River Great Ouse and its tributaries enables one to trace the true cause of recent changes in bed level and the actual reason for the present silting trouble. Further, the theory enables one to calculate, within limits, the changes in bed which may be anticipated to result from each of the various outfall improvement projects that have been proposed. Finally, it shows the inadvisability of dredging a deeper channel without altering the hydraulic conditions to insure that the greater depth would be hydraulically maintained; and, conversely, that if the hydraulic conditions were properly altered, the dredging would appear to be unnecessary, as the improved hydraulic conditions would insure the required alteration in bed level within the range of strata consisting of loose granular material.

CONCLUSIONS

In summary, the following conclusions regarding this theory of silt transportation are noted:

(1) In a channel carrying a silt load consisting of loose granular material, such as sand, and flowing over a bed of the same material, equilibrium at any point in the bed is governed by the velocity and depth at that point, and by the silt load carried.

(2) If any two of these factors are known, the third one can be computed.

(3) Statements (1) and (2) are true for the channel section as a whole, equilibrium being governed by the mean velocity, mean depth, and average silt load across the section.

(4) A channel flowing under these conditions will tend to flow at one uniform depth across the section, the depth which gives equilibrium independent of the volume of flow.

(5) In the case of a channel carrying only very light material (capable of being carried by all eddies, and classifiable as "colloids") and flowing over a bed of the same material, different conditions pertain and the type of cross-section is then different.

DISCUSSION

Joe W. Johnson,[13] Assoc. M. Am. Soc. C. E. (by letter).—The author extends his previous theory of silt transportation and presents supporting data which, in most cases, show excellent agreement between observed and calculated values of silt load. The theory set forth presents a method which, with certain limitations, appears to permit the silt load of a stream to be computed from easily observed factors. The method should be a valuable aid in many studies concerned with the transportation of sediment.

The various examples given in the paper cover, rather completely, the various conditions that may prevail in practice. Other data which represent conditions slightly different from those presented by the author are given in Table 6. These data were computed from observations made in Italy by Mario Giandotti[14] on the Po River and Francesco Sensidoni[15] on the Reno River, and, in Texas, by O. A. Faris,[16] M. Am. Soc. C. E., on the Brazos River. Unfortunately, only the data of Mr. Faris include a mechanical analysis of the suspended material, thereby permitting colloids to be excluded from consideration.

The observations on the Po River are interesting in that the two gagings were taken in the autumn and in the spring at practically the same stage; yet the total silt load in the latter gaging was about four times that in the former. As mentioned by Professor Giandotti, in the spring gaging the stream carried a large quantity of fine material—material which the author would class as colloids. Referring to Table 6(*a*) it is noted that with the exception of one vertical the calculated value of silt content for the autumn gaging is greater than the observed silt content, although the observed value is for total silt content and, of course, includes colloids. On the other hand, in the spring gaging (Table 6(*b*)) the calculated silt contents are without exception much smaller than the observed silt content, a fact due no doubt to a large quantity of colloidal matter.

Table 6(*c*) gives an analysis of silt distribution in the Reno River, in Italy. In most verticals, very close agreement between observed and calculated values of silt content are noted, although the observed silt load, as in the Po River, includes colloids.

Tables 6(*d*), 6(*e*), and 6(*f*) give calculated and observed values of silt content for the Brazos River, in Texas. In addition to the observed silt content which was retained by a No. 200 sieve, the silt content including colloids is also given. Agreement between observed and calculated mean silt content is good in the verticals near one stream bank but becomes poor as

the opposite bank is approached. Such a condition is probably due to a local distortion in the velocity distribution and will be discussed subsequently.

A factor of more practical importance than whether there is good agreement between calculated and observed mean silt content in the various verticals appears to be whether the total calculated silt load of the stream agrees with the total observed load. Discharges and the observed and calculated silt loads, determined by ordinary methods, for the various canals and rivers for which data were summarized in Tables 1, 2, and 6, are shown in Table 7(*a*). Data from flume studies[17] conducted at the U. S. Waterways Experiment Station, Vicksburg, Miss., are included in Table 7(*b*). As mentioned previously the observed silt loads in the Po and Reno Rivers include colloids, and the difference between observed and calculated values are relatively large; however, except for the March, 1925, gaging in the Po, the Imperial Canals, and Brazos River data do not show agreement appreciably better than the Italian gagings.

* Also Tables 6(*e*) and 6(*f*).

An interesting result may be observed by plotting the data in Table 7, logarithmically, so as to obtain a plot of points representing the silt load calculated according to the author's theory. The Brazos River data failed to plot according to that of the other streams, possibly because of the relatively high value of 1.4 for the velocity-head coefficient,[18] α, at this cross-section. Such a high value for α in an open channel is usually found only where the velocity distribution is greatly distorted by obstructions, bends, etc.

For the given data, which cover a wide range of discharge and location of streams, the silt load of loose, granular material (consisting of material larger than $\frac{1}{500}$ in. in diameter and excluding colloids) expressed, in tons per day, is given by the equation,

$$L = 4.0\, Q^{0.89} \qquad (14)$$

in which Q = discharge, in cubic feet per second. That the silt load (including colloids) of a stream may be many times the load expressed by Equation (14) is evident upon examination of Tables 6(*d*), 6(*e*), and 6(*f*), wherein it is observed that 90% of the suspended silt in the Brazos River consisted of particles small enough to pass the No. 200 sieve and thereby can be classed as colloids. Due to the fact that vertical eddies are perhaps not important in the transportation of very fine material, it is doubtful whether a simple relationship between discharge and the silt load of a stream (including colloids) can be formulated. A viewpoint on this subject, as stated by C. P. Vetter,[19] M. Am. Soc. C. E., is:

[17] "Studies of River Bed Materials and Their Movement, with Special Reference to the Lower Mississippi River," *Paper No. 17*, U. S. Waterways Experiment Station, 1935.

[18] "Velocity-Head Correction for Hydraulic Flow," by Morrough P. O'Brien, M. Am. Soc. C. E., and Joe W. Johnson, Assoc. M. Am. Soc. C. E., *Engineering News-Record*, Vol. 113, No. 7, August 16, 1934, p. 214.

> "As long as the discharge and the slope of the river are constant the intensity of the boundary layer, and the concentration of suspended matter maintained by it, is undoubtedly also constant. The fine material, not available in the bed of the stream for many miles up stream from the point of observation, must originate elsewhere on the river or on its tributaries and it cannot be expected that any fixed relationship should exist between the discharge and the load of the finer material. Bearing in mind that the term, 'saturation,' should probably be used with caution in this connection, the phenomenon can, nevertheless, be illustrated by saying that the stream is saturated with the material freely available in the bed but under-saturated with material finer than that found in the bed.
>
> "Yet another conclusion may be drawn from the above reasoning. If the part of the silt load which lies within the range of sizes abundantly available in the bed bears a fixed relationship to the discharge there is no reason to believe that this relationship will be materially changed if the finer part of the load is partly or entirely eliminated."

In the latter conclusion it might also be noted with reference to the Brazos River data that the load of very fine material may be ten times that of the "loose granular" material and still the load-discharge relationship is not changed provided the abnormal velocity distribution as discussed herein is local in character and responsible for the relatively high value of the calculated load.

The ultimate solution of the problem of transportation of suspended silt appears to be from the approach of fundamental mechanics according to a theory such as that developed by W. Schmidt,[20] enlarged by Professor O'Brien,[21] and applied by J. E. Christiansen,[22] Assoc. M. Am. Soc. C. E. Although the author's theory of silt transportation has little scientific foundation, the important factor is that it apparently "works" and does so under a large variety of conditions. In fact, it describes silt transportation, within certain limits, approximately as well as the Chezy formula describes the flow of water in open channels.

G. W. HOWARD,[23] JUN. AM. SOC. C. E. (by letter).—Any stimulation of thought with regard to a subject as important as silt transportation is indeed welcome. The data presented as a result of the observations on the River Great Ouse and the Hundred Mile River are both interesting and enlightening.

[23] Junior Engr., U. S. Waterways Experiment Station, Vicksburg, Miss.

In considering the application of the author's theory to river-control works, however, it is believed advisable that the term, "river," as used in this paper, be clarified. That the theory which is suitable for the Hundred Mile River may be applied to any other river is questionable. The Hundred Mile River, with its cross-sectional area of about 300 sq ft, is small when compared with the Lower Mississippi, which has a bank-full cross-sectional area of about 200 000 sq ft. The differences in hydraulic elements between the Hundred Mile River and most of the rivers in the United States are so great that this hypothesis of silt transportation should be used cautiously.

Of course, in the development of any theory, it is necessary to make certain basic assumptions. Some type of distribution of grain sizes is essential in formulating an equation. On the other hand, actual observations are of great value when one considers the characteristics of any stream. The remarks by Mr. H. S. Kahai[24] in connection with a silt survey of the channels at the Makhi Weir are pertinent. Mr. Kahai states:

> "The following conclusions were drawn:
>
> "(*A*) That it was not possible to determine a definite position on a vertical in any of the channels under observation to represent the mean velocity, silt charge, and weighted mean diameter for the cross-section."
>
> * * * * *
>
> "(*C*) That the behavior of the quality of silt was so erratic throughout the cross-section that nothing could be said about its position of occurrence."

The only illustration in this report which referred to the study of silt, was a cross-section (approximately 750 sq ft in area) of the Mithrao Canal. The distribution for mean grain size and velocity in the canal were as shown in Fig. 9. The silt, however, had a mean grain diameter of 0.030 mm, which is smaller than that used in developing the author's theory, and falls into the class referred to as "light materials carried in suspension by all eddies." These results show the indefinite tendencies for the movement of silt. This also seems a logical conclusion for practically every stream of appreciable size that draws its silt load from tributaries and is of sufficient cross-sectional area not to be made-to-order.

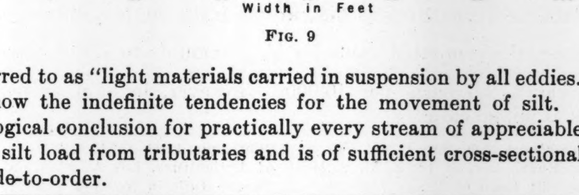

FIG. 9

---

[24] "Report on the Work Done in the Development and Research Division, Sind, for the Year Ending May, 1938," by H. S. Kahai, Executive Engr.

Satisfactory formulas have been derived for various canals in certain localities, but the paucity of data from observations has not permitted the proper approach to the river problem. The magnitude of this problem can be seen from the recent study of variations of suspended silt along the Colorado River.[25] The publication of complete silt surveys and bed-load observations should enlighten the profession on the subject of larger streams to a greater degree within the next few years.

HARRY F. BLANEY,[26] M. AM. SOC. C. E. (by letter).—The theory of silt transportation advanced by Mr. Griffith is of special interest to engineers in the southwestern part of the United States where many of the rivers carry large quantities of silt. In this section one of the most important problems to be solved in designing irrigation and flood-control works properly is that of estimating the silt load carried by the stream. In most instances long-period records of silt measurements are not available, and estimates are based on fragmentary or short-period records. However, long-period stream-flow records may be available and, consequently, the author's method would be valuable in estimating silt loads.

It is noted that Mr. Griffith uses some of the silt studies made by the writer in Imperial Valley, California, and reported[10] in 1928, to illustrate his theory of silt transportation. In reviewing his original field notes the writer has found some unpublished observational data and has used these to check Equation (13). The results are shown in Table 8.

TABLE 8.—ANALYSIS OF SILT DISTRIBUTION IN NO. 5 MAIN CANAL AND EAST HIGHLINE CANAL, IMPERIAL VALLEY, CALIFORNIA

(Observations made on or near center vertical of cross-section)

Name of canal	Width, in feet	Total depth, d, in feet	Velocity, v, in feet per second	Proportion of silt by weight retained by Sieve No. 200, expressed in parts per 10 000 (arithmetic mean)	Values of c_1 in Equation (13)
No. 5 Main...........	32	3.3	3.48	10.3	13.2
No. 5 Main...........	25	3.9	3.79	18.7	13.1
East Highline.........	40	4.6	2.85	8.5	8.9
East Highline.........	40	4.6	1.92	6.9	6.0

Perhaps some of the results[27] of the investigation made by Orville A. Faris, M. Am. Soc. C. E., for the U. S. Bureau of Agricultural Engineering, in Texas, could be used to check Mr. Griffith. The writer does not have access to the original data on Texas streams but, in one instance, for observations on the Brazos River, the computed value for $\frac{7.5\,v}{d^{0.57}}$ amounts to 7.9 as compared with observed value, 9.6 parts per 10 000. However, in another instance, the agreement is not so close.

E. W. LANE,[28] M. AM. SOC. C. E. (by letter).—The author's theory regarding the shape of a channel in erodible material is based on the hypothesis that the fundamental relation between depth and velocity is of the type:

$$B = c\, d^n \qquad (15)$$

There can be little doubt that some such rough relation holds as is shown by the many results obtained by observing stable channels under a wide range of conditions.[29] However, this relation is believed to be an empirical one which gives only approximate results.

The author has used the Chezy equation which has long been known to be unreliable when applied to open channels. If the more reliable Manning's relation is assumed, Mr. Griffith's reasoning indicates that the value of n should be close to 0.67 rather than 0.50.

Mr. Griffith believes that the size of the material of which the banks and bed of a channel are composed does not affect the shape that they will assume, as long as they are of granular material of a fineness between 0.002 in. and shingle. The writer does not believe that any formula can be found covering such a wide range of materials unless the material size is included as a factor. The writer[29] has expressed the belief that the size of the material forming the bed and both the quantity and the size of the load carried by the stream were factors in determining the channel shape. In that paper, emphasis was placed on the importance of the quantity of the material carried since the Lacey formula (which was then under active discussion in India) neglected that factor. Mr. Griffith's relations consider the quantity of material carried, but within the aforementioned very wide range of sizes, ignore the factor of material size and the writer wishes again to urge that both size and quantity are essential factors.

The resistance of granular material to motion by flowing water is closely related to the velocity of settlement in water of the particles of which it is composed. The settling velocity of a particle 0.002 in. in diameter is approximately 0.2 cm per sec, whereas particles 1 in. in diameter would fall about 50 cm per sec, or more than 250 times as fast, and the particles composing a shingle bed might be several times larger than 1 in. in diameter. It does not seem reasonable that beds of such widely different material would act in exactly the same manner.

The writer does not believe that any formula can be found, even for a single stream, that will give the relation between the velocity and depth in any vertical and the total silt load at that point of a size greater than 0.002 in. It is well known that most streams carry widely different suspended loads at the same discharge. For example, at one time, a stream may carry a given load at a certain discharge; and, at another time, it may carry twenty times as much with the same flow.

The quantity of silt carried in an ordinary river channel is composed of two parts, one of which is of the sizes found in the bed, which the river is constantly picking up from the bed and which are also constantly settling to the bottom again. The second part is composed of material brought in by the tributaries which is so fine that it is kept in suspension almost continuously. The river is usually able to carry many times the load of this fine material which the tributaries bring to it. The quantity of this material in suspension at any time, therefore, is usually independent of the nature of the main channel, and depends solely on what the tributaries provide.

---

[28] Associate Director in Chg., Iowa Inst. of Hydr. Research, Univ. of Iowa, Iowa City, Iowa.

[29] "Stable Channels in Erodible Material," by E. W. Lane, *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 126.

For a given river, there is a definite relation between the first part of the load as described herein and the discharge, but since the total load is composed of both parts, and since the second part bears no relation to the discharge, the sum of the two is almost independent of the discharge. If the lower limit of the size of bed material were 0.002 in., the material carried of a size greater than that, being all obtainable from the bed, would have a definite relation to the discharge. However, in most rivers having granular beds, the minimum size of bed material is about 0.005 in. and a large part of the suspended load lies between this size and 0.002 in. In most rivers, therefore, the quantity of this material bears no relation to the discharge or velocity, and the total greater than 0.002 in., since it includes this range, would also bear no relation to them.

In the present state of the knowledge of silt transportation, with the tremendous range of silt concentrations encountered and the inaccuracies that probably exist even in the best silt measurements, differences between observed and computed results which would be intolerable in other branches of engineering science, in this field, may represent important contributions to that science. The relatively excellent agreement of the observed data with the values computed by Mr. Griffith's formulas, however, is believed to be fortuitous.

For example, in Tables 1 and 2 the data are expressed in proportions of silt by weight retained on the 200-(0.0029-in.) mesh sieve, but in Table 3 the percentage retained on the 300-(0.0018-in.) mesh sieve was used. This is the way the data were presented in the original source. A computation from the original data on which Table 3 is based, however, shows that if the 200-mesh sieve had been used as the limit, the results would have been only 60% as great. This indicates that if the division point of Tables 1 and 2 had been at 0.002 in. instead of 0.0029 in., the results would have been roughly 55% larger than those given. Data published elsewhere in the *Bulletin* from which Tables 1, 2, and 3 were taken[10] do not substantiate Mr. Griffith's results. Using the data for the Elder Canal (Table 23),[10] results are obtained giving silt concentrations averaging only 4% of the values given by Mr. Griffith's formula, and, for the Rositas Canal,[10] results averaging only 38 per cent.

O. A. FARIS,[30] M. AM. SOC. C. E. (by letter).—The theory of silt transportation suggested by Mr. Griffith may be applicable under the limitations and conditions which he proscribes; however, it is believed that its application to most of the rivers of Texas will ordinarily lead to serious error. Investigations,[31] under the direction of the writer, include the collection and determination of the silt content of thousands of samples of water from various rivers of Texas, over a 9-yr period. The velocity of the water at the point of sampling was determined in many instances.

---

[30] Engr.-Appraiser, Federal Land Bank of Houston, Houston, Tex.

[31] "The Silt Load of Texas Streams," by Orville A. Faris, *Technical Bulletin No. 382*, U. S. Dept. of Agriculture, 1933.

In sampling a flood originating in the upper regions of a water-shed, at a station farther down stream and out of the storm area which produced the rise, it was found that the first water reaching the station was comparatively free from suspended material. This was due to the arrival of clear water forced out of pools, along the river, by the heavier silt-laden water of the flood. As the stage built up, the silt percentage increased to a certain point and then decreased although the river stage continued to rise. During the falling stage, the percentage of silt again increased to some extent. This secondary increase in silt percentage is believed to be due to the sliding of recently deposited silt, into the stream, from the sloping banks where trees and brush retarded the velocity to the extent that deposition resulted. In some reaches of the streams, the secondary increase in silt percentage is due largely to the caving of banks undercut by the current. The greater part of the silt load, of the streams under observation, is made up in advance by the process of weathering. After a long dry period the first water that runs off picks up the fine weathered material and carries it into the stream. After the first flushing, run-off from the wet area must depend on erosion for its silt load, which is ordinarily light since the part of a large water-shed where excessive erosion occurs is usually small in comparison with the entire area. This accounts for the decrease in silt percentage while the river stage continues to rise.

The character of the part of the water-shed on which a flood originates affects the quantity of silt reaching a down-stream station at equal stages of the river. At Waco, Tex., on the Brazos River, it has been observed that floods from the Bosque River which joins the Brazos about 3 miles up stream from the station, contain a lower percentage of silt, at the same stage, than floods originating on the upper part of the Brazos water-shed.

These investigations led to the conclusion that the total quantity of silt passing a station in these streams, at a given time, is a function of loading rather than velocity and depth of water in the section. It is true that the higher the velocity the greater is the carrying capacity; but, since the capacity load was not even approximately reached and the silt content at a single station varied for equal stages of different floods, the magnitude of the silt charge carried appears to be a function of the loading and not of capacity to carry.

J. E. CHRISTIANSEN,[32] ASSOC. M. AM. SOC. C. E. (by letter).—Following Equation (1) the author states,

> "It is claimed that from Chezy's basic equations of flow for unerodible perimeters, the average velocities in the vertical planes through the points, *A*, *B*, *C*, etc. [Fig. 1], across the section will vary as the square root of the depths at those points; that is, as $d_1^{0.5}$, $D_2^{0.5}$, $d_3^{0.5}$, etc."[3]

This is only a rough approximation at best, and cannot be considered a basic law. Mean velocities in vertical planes of channels with flat bottoms often vary considerably from the center of the channel to sections near the sides. In the Chezy formula,

$$V = C\sqrt{R\,S} \qquad (16)$$

---

[32] Asst. Irrig. Engr., Coll. of Agriculture, Univ. of California, Davis, Calif.

C is not constant; it is a function of S, R, and Kutter's coefficient of rugosity, n, assuming that Kutter's formula represents the relationship correctly. For a given value of Kutter's n, and between limits of R and S, the Kutter-Chezy formula can be approximated closely by simple exponential formulas; for example, for Kutter's $n = 0.0225$, and for slopes greater than 0.0001, the approximate equations are:

For $0.1 < R < 1.0$,

$$V = 66\,R^{0.81}\,S^{0.51} \qquad (17a)$$

for $1.0 < R < 10$,

$$V = 66\,R^{0.69}\,S^{0.51} \qquad (17b)$$

for $10 < R < 100$,

$$V = 74\,R^{0.58}\,S^{0.49} \qquad (17c)$$

Compare Equations (17) with Manning's formula, which for Kutter's $n = 0.0225$ becomes,

$$V = 66\,R^{0.667}\,S^{0.5} \qquad (18)$$

The author's theory of silt transportation is based fundamentally on a formula of the Kennedy type, Equation (1), in which he assumes that c is primarily a function of the quantity of silt carried. If his reasoning from Equation (1) is correct, the value of n should exceed the value of the exponent of R in Equations (17) and (18). Most of the formulas of the Kennedy type[6] involve the use of exponents of d or R less than the values of the exponents of R in these equations, except Equation (17c), which apply up to values of $R < 10$.

The writer believes that undue importance has been attached to the Kennedy formula. In 1927, discussing the prior paper cited by the author,[4] Mr. F. M. Woods stated[33] that Mr. Griffith had relied greatly on the Kennedy formula and had also extended its application to conditions of great rivers in unstable regime, involving every kind of irregularity of flow. The formula was stated to have been consistent with hydraulic data observed by Mr. Kennedy on a limited range of artificial earth canals; but, to extend its application as described would be questionable even if it were correct for canals in stable regime. According to Mr. Wood, Mr. Kennedy had enunciated no original theory, having merely deduced, from observed data, a useful empirical formula in support of theories current in India, which had been enunciated thirty years earlier by Mr. Thomas Login, an engineer on the Ganges Canal. The latter, in turn, was merely confirming, from his own experiences in the Ganges Canal, theories suggested by Mr. J. Dupuit in 1848. Mr. Woods then proceeds to warn that the Kennedy formula, based on "observations of certain Punjab irrigation-canals," has marked limitations despite the fact that it had been a useful guide to the design of canals for thirty years. For example, Mr. Kennedy did not measure the water-surface slope of any of his sample channels; nor did he compute the corresponding values of Kutter's coefficient of rugosity. He evaluated the discharges from discharge tables and the mean velocities by dividing this discharge by the area of cross-section. According to Mr. Woods, even Mr. Kennedy's determination of area of waterway was not quite satisfactory, being expressed in terms of bed width and depth, without reference to the inclination of the side slopes.

---

[33] "A Theory of Silt and Scour," by W. M. Griffith, *Minutes of Proceedings*, Inst. C. E., Vol. 223 (1927), p. 268.

Since the values of the exponents of d or R in both the silt formulas and general flow-of-water formulas are of approximately the same magnitude, the most logical conclusion would appear to be that the slope, for stable channels, should be primarily a function of the type and quantity of silt to be carried. Equating Kennedy's and Manning's formula:

$$C\,d^{0.64} = \frac{1.486\,R^{0.667}\,S^{0.5}}{n} \qquad (19)$$

from which,

$$S = \frac{C^2\,n^2}{2.21}\left(\frac{d^{0.64}}{R^{0.667}}\right)^2 \qquad (20)$$

Because of the inexactness of the exponents of d and R the ratio, $\frac{d^{0.64}}{R^{0.667}}$, may be assumed to be constant. For a given value of Kutter's n, then:

$$S = K\,C^2 \qquad (21)$$

This leads to the conclusion that a channel may be in stable equilibrium at any depth providing the slope is correct, a conclusion very different from that reached by the author.

The theory of silt distribution developed by W. Schmidt[34] and M. P. O'Brien, Assoc. M. Am. Soc. C. E.,[35] has been checked against some of the same data[36] used by the author, with a correlation equally as good. This theory does not account for the concentration of silt in suspension, or that which is moved along the bottom; but it does show that the distribution of silt within the section is a function of the size of the silt particles and the turbulence of the stream. From this theory, it would appear questionable to attempt to divide silt arbitrarily into "colloids" which are "carried in suspension by all eddies" and "loose granular material" that is "dependent on the vertical eddies alone." What may be "colloids" in one case may be "loose granular material" in another case, with a different degree of turbulence.

E. W. Lane,[37] M. Am. Soc. C. E., has called attention to the correlation between the quantity of coarse material in suspension and the discharge of a given stream, and the apparent lack of any correlation between the very fine material and the discharge. He attributes this condition to a balance between the kind of material in the bed of the channel and that in suspension. The percentage of very fine material in suspension, of which there is little in the bed material, is governed primarily by the source of such material. The writer came to essentially this same conclusion when studying silt data from the

Colorado River where high concentrations of fine material generally occur during the fall of year when the discharge of the Lower Colorado is fairly low. These high concentrations of fine material coincide, however, with the period of thunder-storms in desert areas, and with the flashy peak discharges of some of the lower tributaries that bring this material into the Colorado River. The concentration of the coarser material coincides fairly well with the discharge, but appears also to depend upon whether the river stage is falling or rising. With a sustained high discharge, the concentration of coarse material generally decreases.

SAMUEL SHULITS,[38] Assoc. M. AM. Soc. C. E. (by letter).—An empirical approach to the problem of the transportation of solids by streams is presented in this excellent paper. The value of the method outlined lies in its simplicity and its seeming success in fitting existing data. The writer will attempt to subject certain parts of it to a critical analysis, in the hope that more light will be thrown on the fundamental bases of Mr. Griffith's formula.

The statement that Equation (1) is the elementary law of silt transportation seems to lack rigorous foundation. This equation can be regarded as scarcely more than an empirical formula derived from measured data of stable channels by the principles of mathematical curve-fitting. Accordingly, it cannot be vouchsafed the position of a fundamental law. By varying the exponent, n, the equation can be made to fit any set of data. Comparative compilations of such equations by E. W. Lane,[39] M. Am. Soc. C. E., have revealed such wide disagreement between existing formulas of this type that their practical reliability is rather uncertain. The thoughts expressed in this paragraph also apply to Equation (2).

When it is remembered that Chezy's velocity formula is based on the arbitrary assumption that the tractive force is porportional to the square of the mean velocity, it would appear that the criterion of $n = 0.5$ for equilibrium (or for channel stability) may not be well founded. Furthermore, since the tractive force is equal to $w\,R\,S$ (in which w is the unit weight of water; R, the hydraulic radius; and S, the energy gradient), considerable error may be incurred by substituting the mean depth, d_m, for the hydraulic radius, especially in small channels.

In natural channels the movement of material on the bed is limited to a strip approximately in the center, no movement occurring near the sides. This has been shown by field measurements made by S. Kurzmann[40] and explained experimentally by A Schoklitsch [41, 42] These results are at variance with Mr. Griffith's deductions that bed movement exists only where his depth criterion based on $n=0.5$ is exceeded. Actual measurements to substantiate the hypothesis would be extremely valuable.

[42] Stauraumverlandung und Kolkabwehr," by A. Schoklitsch, Vienna, Julius Springer, 1935.

It is interesting to consider the significance of the stated possibility of mathematical calculation of *f*, the ratio of the cross-sectional mean velocity to the mean velocity in a particular vertical. This connotes that the mean velocity in any vertical of a cross-section can be predicted accurately.

Tables 1 to 4 merely show that Equation (13) fits the particular data well. One wonders if measurements in a tidal channel with its complex flow conditions should be used as the basis of a general formula, particularly when agreement was achieved by using the surface velocity instead of the mean velocity, a procedure amounting to an arbitrary 25% correction.

It is difficult to conceive a formula for solids transportation that does not include the effect of size of particles carried. The variation with discharge of the particle size for channel stability has been demonstrated elsewhere[43] to be of appreciable magnitude.

The practical application of the Griffith formula (Equation (13)), necessitates ultimately a knowledge of the mean velocity in various verticals—an exceedingly difficult physical quantity to predict with reasonable accuracy.

Although the evidence is scientifically meager, the method presented in the paper seems to yield useful results. The approach is representative of the time-honored hydraulic method and stands in contradistinction to the contemporary technique of fluid mechanics as incorporated in the works of Messrs. W. Schmidt,[34] M. P. O'Brien,[35] and J. E. Christiansen,[36] on the subject of solids transportation. The writer leans toward the latter concepts in the belief that, in the end, they will be more fruitful. The contemporary experiments of fluid mechanics are broadening the language of hydraulics. Then, after a long period of development this new language, this new body of concepts, will be such a natural part of an engineer's intellectual equipment that he should be able to create and not merely conjecture with it.

Gerald Lacey,[44] Esq. (by letter).—Canal engineers in India who have made a study of silt transportation will read this paper with great interest. The writer was rather disappointed to find that the author had not modified his opinions expressed in 1927.[2] The writer had hoped that two contributions of his own on this subject[45] might have induced Mr. Griffith to reconsider his views. The part of Mr. Griffith's paper dealing with silt charge is of value as an interesting and original attempt at a quantitative solution.

When the author broadly refers to changes in the cross-sections of rivers and canals that could be computed mathematically by a "single elementary law" (see heading, "The General Theory") he is possibly representing the subject as being simpler than it really is. Furthermore, when Mr. Griffith proceeds to argue by reference to "Chezy's basic equations of flow" without expressing them mathematically, he is on debatable ground.

[45] "Stable Channels in Alluvium," by Gerald Lacy, *Minutes of Proceedings*, Inst. C. E., Vol. 229; and "Uniform Flow in Alluvial Rivers and Canals," *Loc. cit.*, Vol. 237.

It is of interest to trace the subject historically. The classic equation is that proposed by Kennedy[5] in 1895,

$$V = 0.84\, d^{0.64} \ldots\ldots\ldots\ldots (22)$$

Kennedy was of the opinion that in silt-transporting channels the bed was practically horizontal and the sides practically vertical. In Equation (22), therefore, V represents the mean velocity of the entire cross-section and d the average vertical depth as measured on the horizontal part of the bed. Kennedy described his equation as an empirical relationship, and although some attempt was made in his paper to deduce expressions having reference to silt charge, the equation was a practical engineer's empirical formula and of most value when used with discretion and applied to channels in India within the range of Kennedy's observations. Kennedy's paper was published without discussion by the Institution of Civil Engineers, London and, by the irony of fate, has been discussed almost without intermission ever since.

In 1912, Mr. W. J. Howley,[46] taking into account the fact that the side slopes in Madras, India, were not always vertical, preferred to deal with the mean vertical depth (the cross-sectional area divided by the water width) rather than the vertical depth, and produced for Madras the new equation,

$$V = 0.72\, d_m{}^{0.55} \ldots\ldots\ldots\ldots (23)$$

Both these equations are of importance inasmuch as they deal (very sensibly, in the writer's opinion) with the mean velocity, throughout a cross-section, and no attempt was made to draw inferences from such a generalized equation, as to the mean velocities in any given vertical.

In 1926, the writer[47] found that by treating the hydraulic mean depth, **R**, as a variable that the Kennedy equation could be replaced by the expression,

$$V = 1.16\, \mathbf{R}^{0.5} \ldots\ldots\ldots\ldots (24)$$

and, in 1930, demonstrated that both the Madras and the Kennedy data could be represented with accuracy by the general equation,

$$V = c\, \mathbf{R}^{0.5} \ldots\ldots\ldots\ldots (25)$$

In 1930 Mr. Griffith,[48] adopting the Kennedy equation as modified by Howley, and following the writer's expedient of reconciling the Kennedy and Madras data, obtained the expression for the mean velocity that is introduced in this paper as Equation (9).

From the practical engineer's viewpoint it makes little difference whether the writer's equation or that by Mr. Griffith is used. All the results that Mr. Griffith claims for his expression can be obtained as accurately and more readily by using the equation involving the hydraulic mean depth. B. A. Etcheverry, M. Am. Soc. C. E., has dealt with the subject competently and fully.[49]

[49] "Land Drainage and Flood Protection," by B. A. Etcheverry, 1931, see heading, "Problems of Flow in River Channels."

The arguments advanced for using the mean vertical depth, d_m, rather than the hydraulic mean depth, **R**, as a variable, are shared by other engineers of the Kennedy school. Mr. Griffith, however, presents an original argument as to why the power of d_m should be greater than 0.5 in his equation.

The Chezy equation can be written in the form,

$$V = C \sqrt{R\,S} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (26)$$

Experience has shown that the expression is incorrect. For regime channels there is now a great mass of evidence to show that for alluvial material of constant grade the equation,

$$V = C\,R^{0.75}\,S^{0.50} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (27)$$

is approximately correct. That the Manning equation,

$$V = C\,R^{2/3}\,S^{1/2} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (28)$$

is superior to the Chezy equation as originally presented, is conceded by every one.

Attempts to apply the Chezy general equation to calculating the mean velocities over verticals appear to the writer an unjustified step. There exists a certain mental confusion between equations of different types. Thus, when the writer first published his equation,[50]

$$V = C\,R^{0.5} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (29)$$

for regime channels, it was argued[51] in India that the writer's equation was a backward step to Chezy. It was contended that the power in Chezy's equation (following Manning) was not $\frac{1}{2}$ but $\frac{2}{3}$ and, therefore, the power in the writer's equation was wrong. As a matter of fact there are two relationships, each one correct; namely: $V \propto R^{0.50}$; and, $V \propto R^{0.75}\,S^{0.50}$.

It follows, therefore, that in regime channels the slope varies inversely as the square root of the hydraulic mean depth, as the writer has demonstrated statistically.[52]

Mr. Griffith claims from Chezy's "basic equations of flow" that the average velocities in vertical planes above points on the bed should vary as the square roots of the vertical depths. If the original Chezy equation is used, it is wrong; if, on the other hand, Chezy as corrected (Manning, for example) is used, the power $\frac{2}{3}$ is greater than 0.57 and, therefore, Mr. Griffith's channels should perform in a manner opposite to that which he predicts. The point, however, is of little importance as the propriety of the entire line of argument is in doubt. Whether or not channels in incoherent alluvium widen depends on the simple relationship connecting the wetted perimeter, P, and the discharge,

$$P = 2.67\,Q^{0.50} \ldots\ldots\ldots\ldots\ldots\ldots\ldots (30)$$

a relationship first evolved by the writer[53] in 1928 and confirmed by thorough statistical analysis of data analyzed in Sind and the Punjab.[54] The value of the constant varies from 2.5 to 2.8, the power is invariably 0.50.

There appears little doubt that the correct variable to use is the hydraulic mean depth, **R**, rather than the mean depth. It is true that silt is suspended by vertical components of eddies; but the section is generated by forces normal at all points to the wetted perimeter, and there is every reason why the hydraulic mean depth should be retained unless some other variable, without recourse to argumentation, can be proved statistically preferable.

Instead of Equation (11), the writer would use the equation,

$$\mathbf{R}_2 = \mathbf{R}_1 \left(\frac{P_1}{P_2}\right)^{2/3} \qquad (31)$$

Unfortunately, Mr. Griffith failed to quote (see "Application of Theory") the fundamental wetted perimeter, P, or the mean hydraulic depth, **R**. The writer would be grateful if Mr. Griffith would supply the missing values of P and **R** and also compare and quote the accuracy of the result obtained by using Equation (31).

The theory offered by Mr. Griffith in respect of silt charge is original and valuable. To the writer it appears that the theory would be improved by using his own simple equation: Silt factor $\propto \frac{V^2}{\mathbf{R}}$.

The silt in suspension is a function of the turbulence, or as V. V. Tchikoff, M. Am. Soc. C. E., terms[55] it, "kineticity." For this turbulence Mr. Griffith presents the ratio, $\frac{V}{d_m^{0.57}}$, instead of the writer's $\frac{V}{\mathbf{R}^{0.50}}$.

The ratio, $\frac{V^2}{\mathbf{R}}$, has the dimensions of an acceleration and has a physical meaning associated with turbulence, or "vorticity," whereas the expression, $\frac{V}{d_m^{0.57}}$, is dimensionally unsatisfactory and, from a practical standpoint, somewhat unmanageable.

With much of Mr. Griffith's general views the writer is in agreement, but he feels that little progress can be made in fundamental theory by retaining the mean depth as a variable or by relying too implicitly on a doubtful interpretation of Chezy's equation.

GLENN W. HOLMES,[56] JUN. AM. SOC. C. E. (by letter).—Under the conditions established and on the assumptions made, the author's theory of silt transportation seems both logical and reasonable. In practice, however, the writer believes the conditions would rarely be met and the assumptions in general would not be found valid.

If the velocity in the center of a section exceeds that required for equilibrium as defined by the author, it will necessarily incline to scour. It does not follow, however, that the sides will shoal as the author claims. The scoured material is carried down stream and not directly to the sides, and the correspondingly reduced marginal velocity may not be slow enough to cause deposition of material coming from up stream.

[55] *Transactions*, Am. Soc. C. E., Vol. 102 (1937), p. 167.

[56] Associate Hydr. Engr., Soil Conservation Service, Washington, D. C.

In 1925, Fred C. Scobey and the late Samuel Fortier, Members, Am. Soc. C. E., wrote:[57]

> "* * *. It has been considered that for each depth of water there is a certain velocity below which silt will be deposited and above which silt will be eroded from the bed of the channel. In the opinion of the writers, two phenomena only slightly related are thus confused. The power of flowing water to maintain a movement of separate soil, sand, or gravel particles, has been confused with the power to break the bedding of a canal bottom and ravel off particles of that bed and transport them to places of lesser velocities where they may be deposited. In their [Messrs. Fortier and Scobey] opinion there is no sharp line of demarcation between the velocities that can no longer maintain silt in movement and those that will scour a canal bed. It is believed that there is a broad belt of velocities between these two 'critical' velocities, within which silt already loosened or brought in through a head-gate will remain in suspension while the bed nevertheless will remain undisturbed as regards scour. It is easy to show the absurdity of accepting the laws of silting as giving the immediate answer to the laws of scour."

The inertia of particles in bed material, the cohesion, adhesion, mechanical interlocking, and other properties all contribute to a resisting force opposed to scouring—such resistance not having a counterpart in the forces opposed to transportation once the particles are in motion.

It would seem to the writer that clear streams and mud flows both deny the existence of definite critical velocities above which scouring occurs abruptly and below which sedimentation suddenly takes place.

Whether or not the author is correct in assuming such critical velocities or conditions of equilibrium, it is believed he attempts too great a step in applying his theory, based on a particular size range, to the measurement of the entire silt load of a stream. To be applicable to such a problem it is necessary to assume that there is a dependable relationship between total load and the part comprised of particles of sizes greater than 0.002 in. Table 9 shows the results of mechanical analyses made of silt samples collected by the U. S. Geological Survey for the Soil Conservation Service at four stream-gaging and silt-sampling stations. It is clearly shown that there was wide variation in the proportion of particles greater than 0.002 in., not only for different streams but also for different observations of the same stream. Although the samples were taken to represent the cross-sections at the time of observation, they were in other respects, without going into detail, essentially random samples. It should be noted also that the larger silt particles made up only a small part of total loads.

The author states that the particles finer than 0.002 in. will not affect the bulk of the bed lining of channels in which loose granular material is being transported. This may or may not be true for channels or rivers in general; but if the theory is to be used to measure entire silt loads that may endanger the life of reservoirs or other slack-water sections, the particles larger than 0.002 in. are often found to play minor rôles in damages as may be seen in Table 10 prepared from information presented by the late Henry M. Eakin[58] in 1936. Mr. Eakin wrote:

* "Silting of Reservoirs," by Henry M. Eakin, U. S. Dept. of Agriculture, *Technical Bulletin No. 524*, July, 1936.

It seems probable to the writer that no simple formula involving such factors as velocity and depth will be found to define silt loads of any particular size or range of sizes, because in addition to reasons already stated, those factors do not, and cannot, regulate or indicate the rate of débris supply, largely soil erosion, which is known to be a complicated process in itself.

Hunter Rouse,[59] Assoc. M. Am. Soc. C. E. (by letter).—"Theory" is a word which has come to possess several distinct connotations. Among scientists, theories are generally based upon reasonably sound physical analysis; many such theories of past decades have become the natural laws of present-day science, after having stood the test of thorough experimental observation. Although many engineers adhere to the scientific meaning of the word, in general practice numerous so-called theories vary from sheer hypotheses with neither analytical nor experimental foundation to concepts based upon either imperfect or totally erroneous methods of reasoning; as a result, more than one practical engineer has come to regard the word "theoretical" as the antonym of "actual." What is meant by "theory" in the present paper must be judged from the fact that it is based upon "two assumptions" and an "elementary law," the latter apparently having no more foundation than the two assumptions.

If Equation (1), the "elementary law," was developed on the basis of experimental data, it is a true empirical formula; if it was first formulated and subjected later to experimental check, it apparently began as a pure hypothesis. In neither case could it be considered to embody a scientific theory, and to regard it as a basic law is to presume that every possible experimental test had confirmed its validity. Since the author gives no reasonable physical justification for this initial statement, it would appear to be a purely arbitrary formula, which can be made to fit experimental data by adjustment of a variable coefficient and a variable exponent—as could other relationships of different mathematical form. The expression is really not as simple as it appears, for it embodies implicitly these two additional unknown functions.

Equation (2), again, may "follow from Equation (1)," but only if f bears the brunt of the change. This factor depends not only upon the shape of the cross-section, as the author states, but also upon the relative roughness of the bed and the mean velocity of the flow. For instance, f is surely not unity for a rectangular cross-section unless the width-depth ratio is large, as may be seen from any measured pattern of isovels. Perhaps f may be estimated empirically with sufficient accuracy for practical purposes; but if this factor can be "mathematically determined for any known type of cross-section," it is by a method as yet unknown to the writer. Equations (3) to (9) are subject to the same criticisms as Equations (1) and (2).

It would seem to the writer that the author's initial relationship could be classed with the dozen or more empirical formulas for bed-load transport, if used in the form

$$G = c_1 v = \frac{z\, v^2}{d^n} \qquad \text{(32)}$$

to predict the amount of material carried per unit time and per unit width of flow section. It may be written in other forms, of course, by substituting from the equation for tractive force

---

[59] Associate Hydr. Engr., Soil Conservation Service; Asst. Prof. of Fluid Mechanics, California Inst. of Technology, Pasadena, Calif.

$$T = w\,d\,S \quad\text{.........................}(33)$$

and from the Chézy relationship

$$v = C\sqrt{d\,S} \quad\text{.........................}(34)$$

This presumes, to be sure, that the flow is uniform and steady and that the channel is very wide, v and d then being mean values in accordance with the true significance of the Chézy equation. The author, however, recommends its use for individual elements of a cross-section of irregular form, for cases of non-uniform and unsteady flow, and for the transportation of suspended load as well as bed load—indicating, moreover, that z and n will remain essentially constant under all these conditions. No bed-load investigator, to the writer's knowledge, has dared predict that his own formula would include even one of these departures from the normally assumed conditions of motion.

The writer does not wish to be interpreted as being against the empirical method of attack. The method is of extremely great importance to engineering practice, and in specific cases is even more likely to yield immediately useful results than methods which are purely rational. The problem is far more complex than the author's treatment would indicate, however, and the very complexity which prevents a rational solution also stands in the way of a general empirical treatment. With proper adjustment of coefficient and exponent, the equation in question will undoubtedly yield satisfactory results in many instances, and the author is only to be encouraged in studying the variation of these factors with boundary, flow, and sediment parameters. What the writer does protest is the acceptance of an apparently unfounded relationship as a cure-all for the thousand and one ills of the sediment problem, without thorough check. If the theory really has a sound physical basis, it is unfortunate that this was not demonstrated in the present paper.

S. G. Bauer,[60] Esq. (by letter).—As an attempt to discover the influences determining the shape of a stable channel by studying equilibrium considerations, this paper is exceedingly interesting. No doubt it would be quite impossible to take into account all the factors that might influence the cross-section of a channel so that simplifying assumptions must be made. The author's deductions from his assumptions are certainly most interesting and show that the principle is a step in the right direction. His assumptions, however, cannot be viewed with quite the same confidence.

In a channel of infinite width and constant depth it would be quite justifiable to consider the vertical components of the turbulence eddies only for the upward movement of the silt; but when considering the shape of a finite channel, with sloping walls, the horizontal components of the eddies should also be taken into account, responsible as they are for the horizontal velocity distribution across the channel. This raises another point. If the mean velocity in any particular vertical plane were proportional to the square root of the depth in that plane the horizontal velocity distribution would be determined by the bed contour only. As the horizontal components of the eddies provide a constant interchange of energy from the faster to the slower flowing water, this appears a very unlikely assumption.

---

[60] Eng. Laboratory, Univ. of Cambridge, Cambridge, England.

Another point is that the mean velocity of the silt charge of a channel is quite different from the mean velocity of the water, because most of the silt is carried near the bottom of the channel where the average forward velocity of the water is only a fraction of its all-round mean velocity. Moreover, the finer silt moves much faster than the coarser silt in the same channel. In consequence, the distribution of the silt charge along a vertical section has a profound influence on the silt-carrying capacity of a channel. The author assumes a silt distribution varying with the square of the depth, irrespective of the nature of the silt charge. This may be the case, approximately, with some types of fine sand on a very smooth bed. The coarser grade of silt is lifted from the ground by a large velocity gradient which results in a higher velocity of flow above a particle than below it, thereby imparting to it a "lift" similar to that of an airplane wing in flight. The type of silt carried must therefore enter into the law of its distribution. The writer's experience with fine sand in a tidal river in North Wales, Great Britain, flowing in its own silt bed, indicates that even with fine sand the silt charge is much heavier near the bottom of the channel than would correspond to the square law. That gravel and boulders are carried along the bed of a river or channel only is common experience.

Apart from that, the silt distribution is strongly influenced by the presence, or otherwise, of large eddies of the type which produce an unevenness of the water surface. There seems to be some critical rate of flow above which such large-scale eddies appear, sometimes covering the entire depth of the channel, and thus changing completely the entire velocity and silt distribution. At a rate of flow at which the water still appears quite smooth, but which is near that critical rate of flow, this large-scale turbulence can often be released by a small disturbance, such as can be made by throwing a stone into the water or disturbing the evenness of the bed with a stick.

This critical condition has been observed by many, no doubt, and should be taken into account in a manner similar to the critical Reynolds number for the flow in pipes. Dimensional analysis may ultimately lead to a solution. Where these large eddies appear, which are of the same order of magnitude as the width of the channel, it is obviously difficult to derive any consistent laws, but it may well be that this condition is actually a limiting one for the stability of the channel itself.

C. C. INGLIS, ESQ.[61] (by letter).—This paper may be divided into two parts: (1) That dealing with quantity of silt transported; and (2) the theory on which the formulas are based.

The part dealing with quantity of silt transported is interesting and likely to be valuable in many ways; but "grade of silt" is normally more important than "quantity of silt being transported," because it is an independent variable, whereas silt charge is a dependent variable, varying with V, d, and time. For this reason, grade cannot be ignored and the coefficient C_1 must be a variable. The effect of temporal changes in velocity must also be taken into account. In the case of the River Indus, silt charge depends on conditions during the previous eight days, during which the silt charge continues to increase on a rising flood. Similarly, on a falling flood the heavy silt charge tends to persist, and all of the excess silt will not deposit for eight days. This effect is shown clearly in Table 4.

---

[61] Director, Central Irrigation and Hydrodynamic Research Station, Poona, India.

The part of the paper dealing with the theory on which the author's formulas are based is not nearly so "happy." In this paper, as in his earlier paper[7] based on Kennedy's formula

$$V = C\,0.84\,d^{0.64} \qquad (35)$$

the author has assumed that there is a simple, experimental, fundamental formula, applicable to the relation between depth and velocity on all verticals across a channel section. This, definitely, is not the case. As a rough approximation, it is a valuable aid, which has been applied widely in India for many years; but since Mr. Gerald Lacey wrote his first paper in 1928 on "Stable Channels in Alluvium"[62] it has been clear that the Kennedy formula was only an approximation, and that velocity and dimensions of channels were related, simply and directly, to hydraulic mean depth, and only indirectly to depth.

The main objection to the Kennedy formula has been that it ignored shape—that is, according to the formula, a channel with a normal silt value expressed by Equation (35) might be 1 000 ft wide and 1 ft deep or 23 ft wide and 10 ft deep.

The author has evolved a method of determining "the section having the maximum silt carrying capacity" by trial and error from his approximate formulas. This shows that he too considers that the shape of a channel may be varied. Where the material is inerodible this is true; but in erodible material, especially where the silt charge is considerable, the channel (as pointed out by E. S. Lindley, M. Am. Soc. C. E., in 1919[63]) is uniquely determined. Mr. Lacey produced the following formulas giving dimensions for regime channels in 1928:[62]

$$P = 2.668\,Q^{1/2} \qquad (36)$$

$$V = 1.17\,\sqrt{f\,R} \qquad (37)$$

$$V = \left(\frac{Q\,f^2}{3.8}\right)^{1/6} \qquad (38)$$

$$R = \frac{0.7305\,V^{1/2}}{f} \qquad (39)$$

and,

$$S = \frac{f^{3/2}}{2\,587\,Q^{1/9}} \qquad (40)$$

[63] "Regime Channels," *Proceedings,* Punjab Eng. Congress, Vol. VII, 1919.

in which f was a silt factor depending on silt grade, but affected by silt charge. From Equations (38) and (39)

$$R = 0.468 \left(\frac{Q}{f}\right)^{1/3} \qquad (41)$$

Mr. Lacey wrote his second paper "Uniform Flow in Alluvial Rivers and Canals"[64] in 1933 and since then he has improved his formulas dimensionally by introducing kinematic viscosity and gravity. Subsequently he modified the exponents of his original, simple formulas, very slightly. It is interesting to compare these results with the formulas derived statistically by the Punjab Irrigation Research Institute from a mass of Punjab data for silts of less than 0.6 mm diameter (see Table 11). The principal difference in the Punjab formulas is the omission of any silt factor. This does not mean, of course, that a silt factor should not enter the formulas—silt must affect the last three formulas and in the writer's opinion also the P–Q relationship—but merely that owing to the small range of silt found in the Punjab Canals and the low powers in which the silt factor enters the equation, it has not been possible to obtain a significant correlation.

TABLE 11.—COMPARISON OF FORMULAS.

Lacey	Punjab Irrigation Research Institute
$P = 2.667\ Q^{1/2}$	$P = 2.80\ Q^{1/2}$
$R = 0.473 \left(\frac{Q}{f}\right)^{1/3}$	$R = 0.47\ Q^{1/3}$
$V = 1.1512\ (f R)^{1/2}$	$V = 1.11\ R^{1/2}$
$S = \frac{f^{5/3}}{1\,858.6\ Q^{1/6}}$	....

The Punjab Irrigation Research Institute have never accepted the Lacey formulas and have produced formulas of their own, which, until recently, have differed considerably from the Lacey formulas. The fact that they have now produced almost similar formulas, after five years of exhaustive and painstaking work, shows that the regime relationships derived by Mr. Lacey are fundamental. They are not, however, directly applicable to variable, non-regime conditions; and it is for non-regime conditions that approximate formulas of the type evolved by the author are valuable.

W. M. GRIFFITH,[65] ESQ. (by letter).—It is to be regretted that the abbreviated exposition given of this theory has lead to a misunderstanding of its physical basis and of the method by which it was derived. It was not, as has been assumed, based on Kennedy's empirical equation for the Barrey Doale Canals, or any subsequent equations of the same type; it was derived independently from the writer's observations during many years of experience in the training of rivers and in dealing with the problems of some of the heavier silt-laden canals of the United Provinces (India). The writer appreciates the suggestion of Professors Shulits and Rouse that the arbitrary value of the exponent "n" in Equation (1) prevents definite scientific test of the correctness of the elementary law on which this theory is based. To meet the general misunderstanding that has been created it is necessary to give a more complete explanation of this theory and the evidence on which it rests. Furthermore, to enable the theory to be fully tested the writer has added one equation not hitherto published, which definitely connects the value of "n" with the hydrallic conditions pertaining, to enable the mathematical deductions from his elementary law to be checked against observed natural phenomena over a wide range of conditions. This should answer most of the questions raised in discussion.

---

[64] *Minutes of Proceedings*, Inst. C. E., Vol. 237 (1933–34), Pt. 1, p. 421.

[65] Cambridge, England.

Mr. Christiansen demonstrates that, accepting the Kutter-Chézy formulas as giving correct results in formulas of the Manning type, the exponent of R will vary materially with the value of R itself. This does not appear to support the contention that Manning formulas should supersede Chézy's equation as a basic equation of flow, or Mr. Lacey's suggestion that the exponent of R should be $\frac{3}{4}$ and not $\frac{2}{3}$. As the question of what is the basic equation of flow appears to be controversial, the writer's claim that the average velocities in the vertical of streamlines d_1, d_2, d_3, etc., across an unerodible section (Fig. 1), will tend to vary as $\sqrt{d_1}$, $\sqrt{d_2}$, $\sqrt{d_3}$, etc. will perhaps be better appreciated if it is considered that these streamlines are all models of one streamline but plotted to different vertical scales. These vertical scales then will be proportional to the depths d_1, d_2, d_3, etc. As it is accepted that, in models, the velocities will vary as the square root of the vertical scale, it is reasonable to argue that the velocities across the section will tend to vary as $\sqrt{d_1}$, $\sqrt{d_2}$, $\sqrt{d_3}$, etc.

Professor Rouse was not correct in suggesting that the theory was advanced for non-uniform and unsteady flow. Condition (3) stipulates that "the flow is turbulent and follows the boundary surfaces." This was meant to specify sinuous flow within streamline surfaces. To make this point clear one may divide sinuous or turbulent flow into two classes:

(1) Streamline flow, or the lines of flow following the boundary surfaces, flow being steady and uniform; and,

(2) Non-streamline flow, a condition occurring at a sudden enlargement, or other deviation of the boundary surface from the straight line, too rapid for the lines of flow to follow. In this condition, loss of head, by what is termed "shock," occurs, the energy being dissipated by vortices at the point of deviation.

The flow in a canal is usually designed to be streamlined, and therefore Equation (1) will normally hold; but sometimes there is a sudden expansion, perhaps below a tight bridge, and flow will not follow the boundary surface. At this point a scour hole will be found in the bed, the depth of which will not be found to agree with Equation (1). What has happened is that at this point the release of energy, due to the head lost by shock, provides additional turbulence, and the values of c and d are increased temporarily. Beyond the area where this energy is dissipated, the value of $\frac{v}{d^n}$ will fail to support this additional silt charge so that the excess is deposited, causing a hump in the bed, Beyond this latter area, in turn, the value of c having become normal, Equation (1) will again hold.

However, if the expansion is sufficiently gradual to insure streamlined flow, instead of bed scour, it will be found that, as the sides expand, the bed rises, in accordance with values found by Equation (6a), as occurred in the example given of the Hundred Foot River, and *vice versa*. As the radius of curvature of a bend in an artificial channel is usually sufficient to insure streamlined flow, the cross-section at a canal bend generally will be found to be as sketched in Fig. 10.

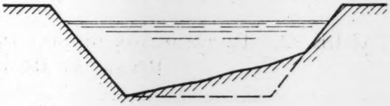

FIG. 10.

Allowing for the decreasing value of the velocity from the outer to the inner margins of the bend, Equation (1) will be found to hold across the section. The writer believes this to be the true explanation of the greater depth observable at the outer margin, and the shoaling along the inner margin, of a bend.

In a river, the radius of curvature of the bends are often insufficient so that the lines of flow cease to follow the inner margin of the bend. This results in loss of head by shock and scour, and then the creation of a hump and an irregular bed generally.

However, the fact that river channels are badly streamlined does not prevent the application of this theory to the general solution of silting problems any more than it prevents the general application of Chézy's formulas to problems of flow. In general, as turbulence for the same velocity will be greater in a river channel than in a streamlined canal, a river should carry a heavier silt charge than a canal for the same values of V and d. From Table 3 it will be seen that the silt charge carried by the Colorado River is greater than that for the Imperial Valley canals for the same values of V and d.

Professor Lane points out that in most rivers the minimum size of bed material is about 0.005 in. Elsewhere, he[66] has shown that at about this size of particle there is a change in the laws governing the rate of settlement of particles in still water. The writer suggested 0.002 in. as the limiting size for classification as loose granular material for rivers, because this appeared to be the limiting size of the actual bed material in the Colorado River and Imperial Valley canals, which carry very fine silt. This was not meant to imply that 0.002 in. was the limiting size for material classifiable as "loose granular" in all rivers. In any river or canal the limiting size that can classify as "loose granular," under the writer's theory, is the limiting size of the actual bed material of that river or canal.

The silt samples of the Central Main and Dahlia canals given in Tables 1 and 2, screened to a 200-mesh sieve, had a much smaller percentage of material passing that sieve than the canals of Table 3, for which the silt samples were screened to a 300-mesh sieve. This is presumably the reason why it was not considered necessary to screen these below the 200-mesh sieve, and why the results of both sets agreed reasonably well with Equation (13).

---

[66] *Transactions*, Am. Geophysical Union, 1938.

Mr. Faris refers to the investigation of silt loads of the Texas streams, concerning which many valuable data have been obtained. Elsewhere, he has presented a comprehensive silt analysis of the cross-section of Brazos River at Rosenberg, Tex., together with data of velocities and depths.[67] These data are summarized in Table 12. In Column (5), Table 12, is given the loose granular contents retained by Sieve No. 300, and in Column (7), the total silt load, both being expressed in parts per 10 000. Column (6), Table 12, contains the loose granular contents computed by Equation (13). It will be seen from this table that, of a total silt content of 76.85 parts per 10 000, the mean observed loose granular content was 7.9 parts as against a computed value, by Equation (13), of 7.3 parts. This agreement appears to be close and justifies the application of this theory to the rivers of Texas.

Mr. Christiansen equates Kennedy's empirical equation and Manning's formulas and argues from this equation that a channel may be in stable equilibrium at any depth, provided the slope is correct. This is not contrary to the writer's conclusions. It will be shown subsequently, however, that there is only one depth of flow which will give the maximum silt-carrying capacity for a channel.

The writer's observation does not agree with Professor Shulits' contention that in natural channels the movement of material on the bed is limited to a strip approximately in the center of the bed, and that no movement occurs near the sides. If this were true, the sides of natural channels must always remain stable, because when there is no movement of material there is no scour or silting. The writer's experience has always been that natural channels in loose granular materials are not stable and have unstable sides.

Mr. Lacey was not correct in assuming that the writer had aopted Kennedy's equation as modified by Howley. Equation (2) was derived mathematically from his elementary law, as explained in his previous paper published in 1927.[2] He then analyzed Kennedy's data in terms of d_m to evaluate n, and again in 1930, when Howley's data were published, evaluated n from both. This evaluation ($n = 0.57$) was only true for a limited set of hydraulic conditions. It will be shown subsequently that Equation (43*b*) gives an evaluation that covers the widest range of conditions.

---

[67] "The Silt Load of Texas Streams," by Orville A. Faris, *Technical Bulletin No. 382*, U. S. Dept. of Agriculture, 1933, Table 5.

The difference between Equation (2) and Mr. Lacey's Equation (29) was fundamental because it could be shown mathematically[68] that the behavior of eddies created by the friction of flow past the wetted perimeter was a function of R, the hydraulic mean radius; but the vertical components of the eddies were functions of d_m, the mean depth, and not of R. Mr. Lacey now agrees that silt was suspended by the vertical eddies. Equation (29) appeared to postulate a transportation of silt by all eddies and Equation (2) by the vertical eddies only.

Again, Mr. Lacey's theory,[50] as advanced in 1930, postulated an elliptical section with a perimeter of silt in permanent regime whereas, according to the writer's theory for loose granular matter, permanent equilibrium was possible only with a bed level across the section.

Observations showed that with a perimeter of loose granular material no permanent regime was ever attained, and where sides existed of a material having different physical properties, regime was attained only if the bed was level across the section and not curved or elliptical.

In consequence the writer had seen no reason to modify his original equation in light of Mr. Lacey's later equations. He was indebted to Mr. Lacey's valuable work, however, for a clearer understanding of the conditions to which his theory was applicable and these have been stated in this paper. In fact, the writer was led to the conclusion that there were two different sets of conditions governing silt transportation—one for the heavier class (loose granular matter), the critical velocity for equilibrium depending on d_m^n, and one for light material, which he classed as colloidal held in suspension by all eddies, the critical velocity for equilibrium depending on $R^{0.5}$. He considered that these two conditions were exemplified by the different types of cross-section: (*a*) Rectangular at the head of the canal where loose granular matter governed the conditions; and (*b*), the curved, possibly semi-elliptical, section found at the tail, where the heavy material had passed from the system.

He could not agree that it made little difference whether d_m^n or $R^{0.5}$ were used because, as will be shown subsequently, it is this difference in value between d_m and R of a flowing section which actually determines the most efficient depth for a channel to carry heavy silt.

Mr. Lacey suggests Equation (31) as an alternate to Equation (11); but, he gives no proof of this equation, which appears to be a purely empirical one, and there would appear to be no advantage in substituting an empirical equation for one reasoned mathematically from a natural law.

Mr. Holmes suggests that there is a wide difference between the velocity which will cause accretion and that which will scour. This is not borne out by the writer's observation of loose granular beds. As the writer's theory is not applicable to the calculation of the total silt load, but only the loose granular contents, it is not applicable to problems dealing with the silting of reservoirs. The mathematical equations for determining the value of f in Equation (2) $\left(\text{that is, the ratio } \frac{V_m}{v_m}\right)$ were presented[2] by the writer in 1927.

---

[68] "A Theory of Silt and Scour," by W. M. Griffith, *Minutes of Proceedings*, Inst. C. E., Vol. 223 (1927), pp. 276–277.

The writer agrees with Mr. Inglis that channels with a loose granular perimeter can have no permanent regime. The Punjab formulas, like Mr. Lacey's equations, are based on the function of R and not d_m and, apparently, are purely empirical. As they provide for no variation in silt factor, they appear to be incorrect in form, and to be applicable only to a limited range of conditions. They can have no general application.

The writer agrees that the value of z in Equation (7) might be affected by the grading of the loose granular matter. His value advanced for z (7.5) was not intended to be taken as an absolute value for all grades; it was advanced provisionally for fine sand. Further investigation was necessary to determine whether the value was suitable for coarse sand, and whether it was affected by an over-load of colloidal matter, or other factors.

Mr. Bauer raises the point that the horizontal components of eddies will affect the velocities in the vertical planes. Theoretically, no doubt, this is so, but in practice—especially in canals—this effect is small, except in the vicinity of the sides. In model experiments, where the vertical scale is distorted, the effect is greater, and in model experiments in a flume with a sand bed having gradually expanding or contracting sides, the writer has found that the value of d_m in Equation (6a), found for the different widths, has been somewhat affected by this factor. In practice the effect is so small that it can be neglected in applying these equations for silt transportation.

It is not clear why Mr. Bauer contends that this theory postulates a silt distribution in the vertical varying with the square of the depth. With a bed of sand and some boulders, two classes of an entirely different order in size, the boulders may roll along the bed; but this would be an exceptional case. Even under such circumstances, small boulders, after a flood, have been found wedged in the lattice girder of a bridge, showing they were definitely not traveling along the bed at the time. That large vertical eddies appear to be released periodically in a flowing section is a matter of common observation. The effect, however, does not appear to affect the general theory, as will be seen from the agreement of the data, submitted by the writer and others, of observed silt loads, with those computed by Equation (13).

Basis of the Theory Advanced.—The writer based his theory on his own observations of the following phenomena during a long period of training rivers with beds of loose granular matter:

(a) In all cases, in a flowing section charged with this loose granular material, if the velocity at any point in the cross-section was reduced artifically by weeds, brushwood, or other means, the depth at the point was reduced until equilibrium was again attained, this reduced depth, in some way, corresponding to the reduced velocity;

(*b*) If the velocity was increased, on the other hand, the depth increased; and,

(*c*) If the velocity remained the same but the silt charge was increased, the depth was reduced, and *vice versa*.

Phenomena (*a*), (*b*), and (*c*) lead to the conclusion that at any point in the cross-section, equilibrium of the bed could be expressed by the equation

$$V = f(c) \times f(d) \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (42)$$

in which V is the mean velocity in the vertical for equilibrium, d the depth, and c a factor representing the silt charge in magnitude. In consequence the writer was led, as early as 1912, to the conclusion that Equation (1) was a natural law, expressing the relationship between velocities and depths at any point in a flowing cross-section. This led also to the second of the writer's assumptions: namely, that the level of the bed at every point is governed by the law of silt transportation.

The first of the assumptions (that the transportation of silt is effected by the vertical resultant of eddies) was the result of his conception of the method in which loose granular matter is transported. It differed from the generally accepted theory that the heavier silt is rolled or dragged along the bed. In 1927 he demonstrated that true rolling of particles could occur only in one layer.[2] If the complete layer were rolled, the quantity would be only a small fraction of the heavy silt in motion.

The writer's conception of the transportation of the loose granular matter is that, in general, it is the same as that in which air currents provide transportation for heavier-than-air particles, as exemplified by the glider. This idea is quite different from the conception of bodies being either rolled or dragged along a surface and is one depending mainly on the vertical eddies or the vertical resultant of eddies.

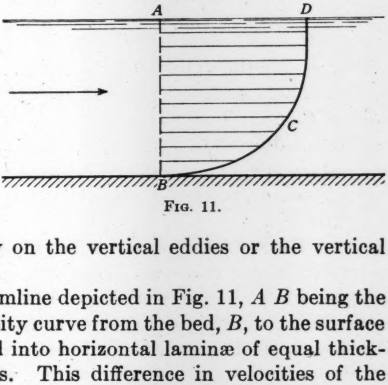

FIG. 11.

Consider a section along some streamline depicted in Fig. 11, A B being the depth and B C D representing the velocity curve from the bed, B, to the surface at Point D. Imagine the fluid divided into horizontal laminæ of equal thickness, all moving at different velocities. This difference in velocities of the laminæ creates eddies normal to their surface—that is, vertical eddies, since horizontal laminæ are being considered. The intensity of these eddies will vary with the rate of change of the velocities of the laminæ.

As the rate of change of velocities of the laminæ is a maximum at the bed and thereafter reduces to the point of maximum velocity, and as the quantity of loose granular matter which the eddies can support will vary with the intensity of these vertical eddies, it is natural to expect a silt distribution in the vertical plane, in general, in accordance with Fig. 2.

All eddies must have a return current and where the maximum velocity is materially below the surface, it is reasonable to assume that these eddies create two sets of rotation—one clockwise, to the line of maximum velocity, and one counter-clockwise, from this point to the surface; and this condition would account for some increase in the intensity of silt charge at the point of maximum velocity where the two sets of eddies meet. This increase in intensity of loose granular matter carried at the line of maximum velocity will be noticed in Table 1 at Station 10 ft and Station 22 ft from the bank.

The Value of n.—As an analysis of the hydraulic data of the boulder-strewn cross-sections of the Jumna River at Kalsi $\left(\text{having a bed slope of } \frac{1}{140}\right)$ gives a value $n = 0.65$,[69] as against a value of from 0.57 to 0.59 given by the analysis of the Madras and Kennedy canal data—and, as the limiting value of n for a minimum turbulence is $n = 0.5$—it is clear that the value of n will increase with the turbulence. This is true also of the value of Kutter's rugosity factor, N, whose limiting value for no turbulence is zero; for the very high turbulence of a boulder bed and very steep bed slope it would be of the order of 0.04 or 0.045.

The foregoing considerations lead the writer to the conclusion that an equation could be obtained connecting the value of n with Kutter's rugosity factor N. Assuming that this is a linear equation, it will be of the form

$$n = 0.5 + A\,N \quad \text{(43a)}$$

From an analysis of data the value of A appears to be 3.33; so Equation (43*a*) becomes:

$$n = 0.5 + 3.33\,N \quad \text{(43b)}$$

For canals the value of Kutter's N is usually accepted as varying between 0.02 and 0.025, and, from Equation (43*b*), this yields values for n equal to from 0.567 to 0.583. These values agree with those found by analysis of the Madras and Kennedy's data. Equation (43*b*) is important because it enables the elementary law, expressed by Equation (1) and other equations mathematically derived from it, to be tested against observed phenomena over the widest range of conditions.

First Test.—Consider first the case of Kennedy's and the Madras data, the hydraulic data of two sets of channels, each set stated to be in regime, carrying approximately the same silt load, but the silt load being different in each set of channels. Values of Kutter's N are not given for these channels, but presumably they will not differ materially and may be assumed to be $N = 0.0225$, giving a value, from Equation (43*b*), of $n = 0.575$. As these canal sections are approximately rectangular, and in any case are all of the same type, f can be neglected, and Equation (2) becomes $V = c(d_m)^n$ or $\left(\text{substituting } \frac{1}{n} = e\right)$;

$$d_m = \left(\frac{V_m}{c}\right)^e \quad \text{(44)}$$

If B = the width at the surface, and Q = the discharge,

$$Q = V_m\,B\,d_m \quad \text{(45)}$$

---

[69] *Minutes of Proceedings*, Inst. C. E., Vol. 229 (1930), p. 322.

From Equations (44) and (45)

$$B = \frac{c^e Q}{(V_m)^{1+e}} \quad \text{(46)}$$

From Equation (44) it will be seen that, for equilibrium, the mean depth of a channel must vary directly as the velocity and inversely as the silt charge, all to the power of $\frac{1}{n}$, and from Equation (46) that the width of the water surface

will vary directly as the discharge and as the silt charge to the power of $\frac{1}{n}$ (= e), and inversely as the velocity to the power of $\frac{n+1}{n}$ (= $1 + e$).

The data, as they apply to Kennedy's channels, are given in Table 13(a) and the Madras channels in Table 13(b). From Column (4), Table 13, it will be seen that with a value of $n = 0.575$ the value of c varies in Kennedy's channels from 0.913 to 1.032 and the mean value is 0.963 (corresponding to a silt charge of loose granular matter of 7.2 parts per 10 000 by weight, from Equation (13), accepting $z = 7.5$ as found for the silt in the canals of the Imperial Valley). In Table 13(a) the width at the water surface (see Column (7)) has been taken as the mean depth, plus one-half the depth given by Kennedy, on the assumption that the side slopes were 1 on $\frac{1}{2}$. The mean depth d_m (Column (5), Table 13(a)) has been computed also from the discharge velocities and depth, as given by Kennedy, on the same assumption. For the Madras channels the value of c varies from 0.642 to 0.71 and has a mean value of 0.682 (corresponding to a silt charge of 5.1 parts of loose granular matter per 10 000 parts by weight)—a much lighter silt charge.

Substituting values of $n = 0.575$ and the values of $c = 0.963$ and 0.682 in Equations (44) and (46):

For Kennedy's channels—

$$d_m = 1.068 \, V_m^{1.74} \qquad (47a)$$

and,

$$B = \frac{Q}{1.068 \, V^{2.74}} = \frac{0.94 \, Q}{(V_m)^{2.74}} \qquad (47b)$$

and, for the Madras channels—

$$d_m = 1.95 \, V_m^{1.74} \qquad (48a)$$

and,

$$B = \frac{Q}{1.95 \, (V_m)^{2.74}} = \frac{0.513 \, Q}{(V_m)^{2.74}} \qquad (48b)$$

In Columns (5) and (7), Table 13, the observed values of d_m and B are given; and in Columns (6) and (8) the computed values derived from Equations (47) and (48) are given for comparison. In general this comparison will be found to support the theory advanced.

Second Test.—Consider next the case of the ratio of depth to width which has been found by practice to give the best results for channels carrying heavy silt loads.

It follows from the basic law that the channel section which has dimensions that give a maximum value for $\frac{V_m}{(d_m)^n}$ will provide the maximum silt-carrying capacity. To test this deduction it is necessary to examine particular cases. Consider three different discharges—100, 1 000, and 5 000 cu ft per sec. It is required to find the type of cross-section that gives the maximum silt-carrying capacity for these discharges. Assume a surface slope of $\frac{1}{4\,000}$ (a sufficient slope to carry a heavy silt load) and side slopes of 1 on 0.5 Assume a value of Kutter's $N = 0.225$, which, by Equation (43b), gives a value of $n = 0.575$.

Table 14 contains the hydraulic data of a number of different sections giving these discharges, computed by the Kutter-Chézy formulas, the values of $\frac{V_m}{(d_m)^n}$ being given in Column (8). By plotting Column (3) against Column (8), it will be seen that: For a discharge of 100 cu ft per sec, a channel 2.5 ft deep has the highest silt-carrying efficiency; for 1 000 cu ft per sec, a 4.5-ft channel has the highest efficiency; and for 5 000 cu ft per sec, a 7-ft to 8-ft channel has the highest efficiency. These results agree with the writer's observations of the heavier silt-laden canals of the United Provinces.

Third Test.—Values of $\frac{d_m}{R}$ in the sub-captions of Table 14 show that the greater the volume of discharge, the nearer this ratio of the most efficient section approaches unity. In the limit, for a section carrying an infinite discharge, the mean depth d_m must equal the hydraulic mean depth, R, and the most efficient depth for a channel carrying an infinite volume will then be that for which $\frac{V_m}{R^n}$ has a maximum value.

Accepting the Kutter-Chézy formulas for flow, it is possible to calculate the mean depth of a channel having the maximum value of $\frac{V_m}{R^n}$ as follows: Kutter's formulas may be written

$$V_m = \frac{a R \sqrt{S}}{\sqrt{R} + b} \qquad (49)$$

in which: S is the surface slope;

$$a = 41.6 + \frac{1.811}{N} + \frac{0.00281}{S} \qquad (50a)$$

and

$$b = \left(41.6 + \frac{0.00281}{S}\right) N \qquad (50b)$$

Therefore

$$\frac{V_m}{R^n} = \frac{a R^{1-n} \sqrt{S}}{\sqrt{R} + b} \qquad (51)$$

Equation (51) has a maximum value when

$$R = b^2 \left(\frac{1 - n}{n - 0.5}\right)^2 \qquad (52)$$

that is, when

$$R = \left(41.6 + \frac{0.00281}{S}\right)^2 N^2 \left(\frac{1 - n}{n - 0.5}\right)^2 \qquad (53)$$

Equation (53), then, gives the most efficient depth for carrying its silt charge for a channel having an infinite volume of discharge. It is reasonable to suppose that rivers of which the perimeter is governed by the silt charge will adopt the most efficient section. Table 15 gives the hydraulic data of some of the largest rivers with surface slopes ranging from $\frac{1}{140}$ to $\frac{1}{15\,700}$ the depths of which will be seen to support Equation (53). For slopes flatter than $\frac{1}{15\,700}$ Equation (53) tends to give too high results, presumably because for very flat slopes the velocities are not sufficient to support the loose granular material and, therefore, the writer's theory cannot hold.

Equation (53) will explain why the depth of a river having an unrestricted perimeter governed by its loose granular silt charge will: (*a*) Tend to increase as the volume of discharge increases; and (*b*), for the same volume of discharge, will increase as the slope reduces.

Mr. Lacey, in analyzing a number of channels that were claimed to be in permanent regime, found that the dimensions of these channels conformed to Equation (36). Mr. Inglis quoted the result of the Punjab investigation[63] which supports this equation, the Punjab equation being $P = 2.80\, Q^{0.5}$ (see Table 11). These equations are purely empirical but they supply strong evidence that some such empirical relationship holds at least within certain limits of hydraulic conditions.

* *Minutes of Proceedings*, Inst. C. E., Vol. 229, p. 327. † Loc. cit., Vol. 223, pp. 256 and 257. ‡ "A General Formula for the Uniform Flow of Water in Rivers and Other Channels," by Ganguillet and Kutter; in English measure by Rudolph Henry and John C. Tunturne, p. 223. § *Loc. cit.*, p. 220.

Referring to Table 14, it will be seen that, for a flow of 100 cu ft per sec, the width at the water surface, B, of the channel section having the maximum silt-carrying capacity, is approximately 25.3 ft, for a flow of 1 000 cu ft per sec, approximately 84.5 ft and, for a flow of 5 000 cu ft per sec, approximately $\frac{195 + 160}{2} = 177.5$ ft. Consequently, the following relations must hold:

Channel flow, in cubic feet per second	Values of B
100	$2.53\ Q^{0.5}$
1 000	$2.67\ Q^{0.5}$
5 000	$2.54\ Q^{0.5}$

This result is important as it appears to establish the law that permanent regime in a channel can be attained only for the sectional dimensions which provide the maximum silt-carrying efficiency. This result is in accordance with nature's tendency for efficiency.

It also gives reason to question whether this relationship should not be some relationship, such as $B = 2.6\ Q^{0.5}$, instead of $P = 2.67\ Q^{0.5}$; and, whether this is a purely empirical relationship or in itself represents a natural law.

Equating $B = 2.6\,Q^{0.5}$ with Equation (46):

$$2.6\,Q^{0.5} = \frac{C^e\,Q}{(V_m)^{1+e}} \qquad (54)$$

Therefore,

$$Q^{0.5} = \frac{2.6\,(V_m)^{1+e}}{C^e} \qquad (55)$$

At first sight this does not appear likely to be more than an accidental relationship holding approximately within a limited range of hydraulic conditions; but the point offers scope for further investigation.

For the last test it will perhaps not be out of place to consider the application of this theory to the silt problem of the All-American Canal.

Some years ago the Hoover Dam was constructed on the Colorado River. It de-silts the river waters completely of both its loose granular and colloidal contents. According to the writer's theory, on leaving this reservoir, the river discharge, to attain equilibrium, must again pick up its full loose granular silt load, to satisfy Equations (2), (7), and (8), provided such content is available in the bed material. Given sufficient length of river-bed to attain this equilibrium, therefore, the discharge should be found to be carrying the same silt load of loose granular material again, for any given velocity and depth of flow, as obtained before the building of this reservoir. A report on the working of this project, dated 1937, indicates that this has been found to be the case.[70]

Consider next the dimensions of the new All-American Canal cross-section given by Professor Lane.[71] The corresponding values of $\frac{V_m}{(d_m)^n}$ (assuming a values of Kutter's $N = 0.0225$, giving a value of $n = 0.575$) are given in Column (6), Table 16, and the values of $\frac{7.5\,V_m}{(d_m)^n}$, the calculated silt load of loose granular matter which these different cross-sections can carry are listed in Column (7).

TABLE 16.—Cross-Sections, All-American Canal

Serial No. (1)	Discharge, in cubic feet per second (2)	Sectional area, in square feet (3)	V_m, in feet per second (4)	d_m, in feet (5)	$\frac{V_m}{(d_m)^{0.575}}$ (6)	Load of loose granular matter, $\frac{7.5\,V_m}{(d_m)^{0.575}}$, expressed in parts per 10 000 (7)
1	15 155	4 041.3	3.75	17.4	0.725	5.44
2	13 155	3 508.0	3.75	16.15	0.758	5.68
3	10 155	2 708.0	3.75	13.77	0.831	6.23
4	7 600	2 171.0	3.50	12.26	0.825	6.18
5	7 400	2 114.0	3.50	12.13	0.834	6.26
6	7 100	2 029.0	3.50	11.86	0.844	6.34
7	6 800	1 943.0	3.50	11.90	0.843	6.33
8	5 100	1 569.0	3.25	10.82	0.824	6.18

It will be seen that in Reaches No. 3 to No. 8 the silt-carrying capacity of the different sections is substantially the same; but the silt-carrying capacity of the head reaches (Nos. 1 and 2) is rather less. Furthermore, the silt-carrying capacity of all sections varies from 5.44 to 6.34 parts per 10 000 of loose granular matter by weight, as against a silt-carrying capacity of the present Imperial Valley Canals of from 9.0 to 12.0 parts per 10 000 by weight (see Column (9) Table 1 and Column (8) Tables 2 and 3).

---

[70] *Engineering News-Record,* March 4, 1937.

[71] "Stable Channels in Erodible Material," by E. W. Lane, *Transactions*, Am. Soc. C. E., Vol. 102 (1937), Table 14, p. 194.

Until such time as the erosion of the river-bed between the Hoover Dam and the head-works of the All-American Canal has materially reduced the slope of the river in this reach, it would appear to be necessary to rely on de-silting works near the head to reduce the loose granular silt load in the river materially, if this canal is to maintain its designed bed without heavy dredging.

For ready reference the principle equations of this theory are given in the Appendix and the writer hopes that they may be of some use to American engineers who have such vast problems of river and canal engineering to solve.

Acknowledgments.—The writer's thanks are due to those who have contributed to the discussion of this paper, especially Mr. Johnson, Professor Lane, and Mr. Blaney, for supplying new and unpublished data and scientific information against which the theory can be checked. Prof. J. Gould, of Cambridge University, Cambridge, England, aided greatly in checking the mathematics. Others, who discussed the paper, cited references of important works by authorities in this field, many of which were new to the writer. It is a source of satisfaction to note that the new data support the theory advanced.

APPENDIX

A summary of the pertinent notation in this paper is as follows: d = depth; d_m = mean depth of the cross-section; v = mean velocity in the vertical, above a point in the bed; v_m = mean velocity in the vertical above the point of mean depth; V_m = mean velocity of the cross-section; $f = \frac{V_m}{v_m}$; Q = the discharge; N = Kutter's rugosity coefficient; n = an exponent (for value see Equation (43*b*); B = width at water surface; c = general silt factor; c_1 = loose granular silt load expressed in terms of parts per 10 000 by weight; z = silt coefficient value = 7.5 for fine sand); S = surface slope; and $e = \frac{1}{n}$.

(*1*) General equations connecting velocity, depth, and silt charge at any point in a cross-section, and for the entire cross-section:

$$v = c\, d^n \quad \text{(1)}$$

$$V_m = f\, c (d_m)^n \quad \text{(2)}$$

(*2*) Equation to obtain the value of Exponent n:

$$n = 0.5 + 3.33\, N \quad \text{(43b)}$$

(*3*) Equation connecting values of widths at water surface and mean depths of two adjoining cross-sections;

(*a*) Similar types of cross-sections—

$$d_{m2} = d_{m1}\left(\frac{B_1}{B_2}\right)^{\frac{1}{n+1}} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6a)$$

(*b*) Dissimilar types of cross-sections—

$$d_{m2} = d_{m1}\left(\frac{f_1 B_1}{f_2 B_2}\right)^{\frac{1}{n+1}} \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (6b)$$

(*4*) Equation connecting silt coefficients:

$$c_1 = Z\,\frac{v}{d^n} = Z\,c\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (7) \text{ and } (8)$$

(*5*) Equations for the mean depth and surface width of canals in equilibrium:

$$d_m = \left(\frac{V_m}{c}\right)^e \quad\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (44)$$

$$B = \frac{c^e}{(V_m)^{1+e}}\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (46)$$

(*6*) Equation giving the most efficient depth of flow to carry the silt charge for an infinite discharge:

$$R = \left(41.6 + \frac{0.00281}{S}\right)^2 \times N^2 \times \left(\frac{1-n}{n-0.5}\right)^2\ldots\ldots\ldots (53)$$

SIPHONS AS WATER-LEVEL REGULATORS

By J. C. Stevens,[1] M. Am. Soc. C. E.

With Discussion by Messrs. A. Griffin, H. P. Currin and D. M. Umphrey, T. J. Corwin, Jr., Henry R. King, and J. C. Stevens.

Synopsis

No novelty attaches to siphons used as wasteways, but the design of siphons for close regulation of water levels, for example, in the forebay of power plants, by discharging continuously through a wide range of flow, marks a distinct advance in such structures and offers opportunities for putting siphons to uses not heretofore contemplated.

This paper describes tests made on two new siphons designed as regulators of the forebay level at the Walterville Hydro-Electric Plant, a unit of the municipal power system of Eugene, Ore. Each of these siphons is capable of discharging continuously any rate between 100% and 3% of its maximum capacity. Working in unison the pair has a maximum discharging capacity of 1 050 cu ft per sec and a minimum of 11 cu ft per sec, so that, considered as a unit, they have a discharging range of from 1% to 100% of their maximum.

The Walterville Siphons

These siphons, two in number, with capacities of 350 and 700 cu ft per sec, respectively, were put into service in the fall of 1936. They replace an old gate and flume waste from the forebay of the Walterville Plant. A part of an overflow spillway was retained by which ice and drift could by-pass the siphons. The discharge from the spillway is carried in an open flume made by extending the sides of the siphon barrel block 4 ft above its top surface. General dimensions of these siphons, in feet, are as follows:

Description	Siphon No. 1	Siphon No. 2
Length of barrel	127.8	123.5
Elevation of overflow crest at summit	595.1	595.0
Elevation of crown at outlet	550.0	550.0
Elevation of top of primer orifice	595.3	595.2

Note.—Published in October, 1938, *Proceedings*.

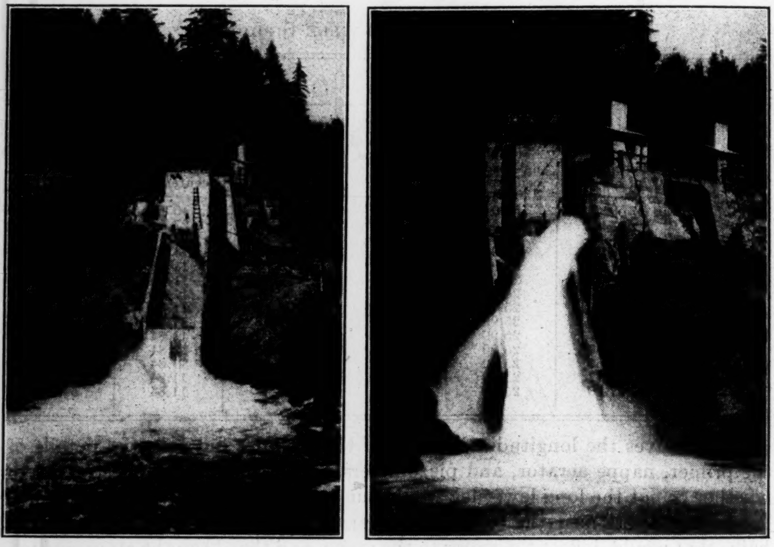
Fig. 1 gives the longitudinal profile of the siphons and essential details of the primer, nappe aerator, and piezometers. There was some question as to whether or not the long lower leg would run full. Therefore, a depression was left in the invert near the end of each barrel in which later a baffle could be built, that would deflect the water to the crown and thus keep the air exhausted from the barrel. Experience indicates that such a device is not necessary, and later these depressions were filled. As long as the siphon does not inhale air the barrel runs full to the end.

The primer is a special feature of this design. It constitutes a discharge regulator since it permits the siphon to inhale air whenever the forebay level drops below the horizontal lip of the primer. As the siphon inhales air the discharge diminishes, until the siphon discharge equals the surplus flow into the forebay. The priming orifices are adjustable both as to depth of opening and as to elevation, and each is provided with a horizontal lip above the orifice to act as a regulator of air supply, and to eliminate the drop-down curve that otherwise would appear as the water accelerates into the priming orifice.

The lower leg is effective in reducing discharge because as flow diminishes this leg runs partly full, the head on the siphon then being from the forebay level to that point in this leg where the water leaves the crown of the barrel.

The nappe aerator was provided inside the barrels just down stream of the summit crest in order to admit air behind the nappe and thus permit it to leave the face of the barrel and fall in a curtain across it, to exhaust the air more quickly. A somewhat similar aerator was included in the Leaburg Siphons.[2]

The piezometers were installed in order to determine the behavior of the siphons for use in future designs. Each piezometer has a copper tube sloping upward from the tap to a manifold on the down-stream face of the siphon block, with a cock in each tube and a connection on the manifold for a vacuum hose. The locations of these manifolds are shown in Figs. 1 and 2(*b*).



(*a*) General View (*b*) Sluice-Gate Discharging Under Full Head

Fig. 2.—Walterville Siphons

One 6-in. pipe with removable cap was provided in Siphon No. 2 and two such pipes in Siphon No. 1 in the summit sections for the purpose of venting the siphons. There is also a vent at the summit of the lower sealing curve to be used for any contingency that might arise.

At Section *A* there are two taps in each siphon in the center of the sides of the barrel. The copper tubing slopes downward from these taps to the point marked *A* on the siphon block (see Fig. 1) where they connect to a header. From this header a rubber hose extends up to a vertical glass tube laid alongside another tube connected to the forebay water. From a scale behind the glass tubes the water level in the forebay and that at Section *A* could be read simultaneously.

Siphon Discharge

Several expedients were adopted to determine the discharge through the siphons during tests. For the higher discharges two methods were used: (1)

---

[2] "On the Behavior of Siphons," by J. C. Stevens, M. Am. Soc. C. E., *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 986.

By means of current meter measurements made in the canal about 3 miles up stream on days when the power plant was shut down; and (2), by means of a Pitot tube in the outlet end of each siphon barrel.

Flow from the forebay into the open wasteway is controlled by stop-planks, the head on which is an index of flow. This measuring device was designated the "stop-log weir." There is also a 30-in. by 30-in. sluice-gate discharging from the forebay. Knowing the forebay level and gate-opening the discharge through it was calculated as for an orifice. The stop-log weir is shown to the left of the siphon block in Fig. 2(*a*), and Fig. 2(*b*) shows the sluice-gate discharging under a full head.

On days when the current meter was used three separate measurements were made about 2 hr apart while a steady canal regimen was maintained. Water in excess of that through the siphon being tested was wasted over the stop-log weir or through the sluice-gate, or both, and was thus measured. Water was also flowing freely over the crest of the unprimed siphon which was calculated as a weir with a rounded crest-ogee type. In addition, there was a small quantity of leakage through the closed gates to the three penstocks which had to be estimated. The discharge through the siphon under test was taken as the average of the three current meter measurements made during that day, less that wasted *via* the sluice-gate, the stop-log weir, the unprimed siphon, and the penstocks. Figs. 3 and 4 show the discharges for the sluice-gate and also for the unprimed siphons. The discharge over the stop-log weir was calculated from the Bazin formula for a crest length of 6.29 ft and a height of 2 ft. A correction of 0.15 h was made in the length to allow for suppressed contraction at one end.

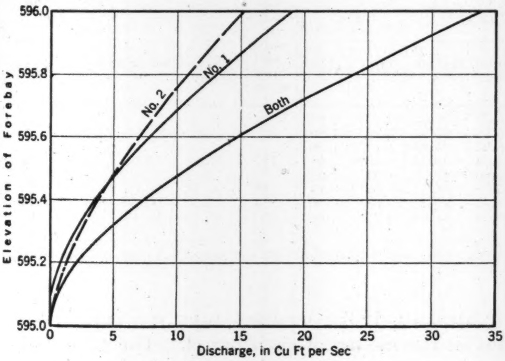


Fig. 3.—Free Discharge Over Siphon Crests

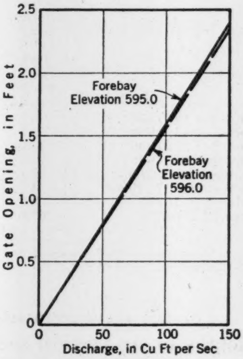

Fig. 4.—Discharge Through Sluice-Gate

For the smaller discharges, current meter measurements were impracticable, and tests were made while the plant was running. Water not taken through the turbines was passed first through the siphon and then changed to the sluice-gate or stop-log weir for measurement. This manipulation involved occasional small variations in forebay level so that some slight canal and forebay storage was involved. For the low discharges that could be taken entirely by the sluice-gate this effect did not exist since the change from sluice-gate to siphon and *vice versa* could be made without affecting the forebay level.

In order to make a check on the canal measurements a frame was set up by which a Pitot tube could be held in any desired position in the outlet with the orifice perpendicular to the direction of flow. The Pitot tube measurements, of course, could be made only for siphons under full discharge with water completely filling the barrel at the outlet. These measurements are more accurate than those by the other methods since the discharge of the siphon under test could be measured directly.

There is a drop in the hydraulic grade line from the forebay level to Section A in which positive pressures exist for all flows. The decrease in area from the Inlet to Section A constitutes an effective Venturi section that was calibrated by observing this drop for each measured discharge. This drop was called the "meter-head" and was designated as H_a; the quantity, $\sqrt{H_a}$, was used as the index of flow. Table 2 gives the results of the various discharge measurements made, including all data required for plotting. A correction of + 0.01 ft was made to low heads, H_a, as it was observed that the piezometer at Section A stood that much above the forebay level with no flow through the siphon.

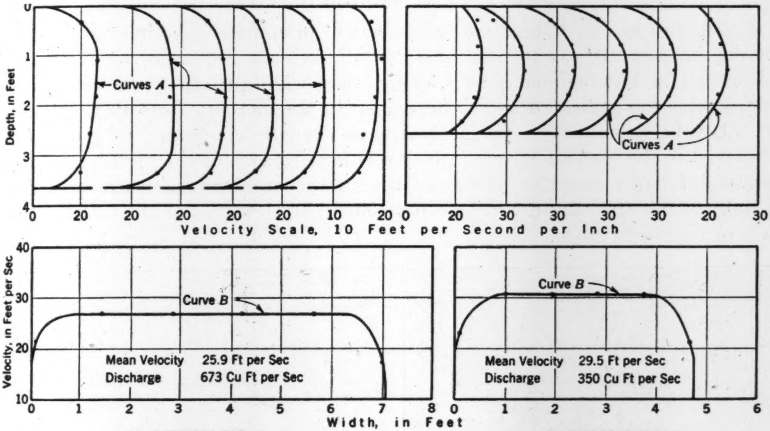
* Current meter method. † Stop-log weir method. ‡ Sluice-gate method. § Pitot tube method.
** Correction, + 0.01 ft.

For the measurements of April 19, 1937, the Pitot tube was held at five depths in six vertical sections in the mouth of each barrel. The tube itself had been rated previously, obtaining a coefficient of 0.98. It was screwed into the end of an extra strong ½-in. pipe. A ¼-in. copper nipple was soldered into this pipe just below the upper end for vacuum hose connection to the mercury manometer. The end was closed with a cork which could be removed to "bleed" the pipe between readings.

Fig. 5(a) gives the results of the Pitot tube measurements for Siphon No. 1, Curve A showing the vertical velocity curves. The mean velocity in each vertical was determined by planimeter; these mean velocities, in turn, determine the plotted points in the horizontal velocity curve (Curve *B*), and the planimetered area of this curve divided by the width gives the mean velocity in the barrel. In similar manner Fig. 5(*b*) gives the results for Siphon No. 2. Comparison with similar curves for the Leaburg siphons[3] shows how the long lower leg has "ironed out" the effect of the up-stream curves.



(*a*) SIPHON NO. 1 (*b*) SIPHON NO. 2

FIG. 5.—RESULTS OF PITOT TUBE MEASUREMENTS

Fig. 6 shows the outlet of the barrels with Siphon No. 1 discharging 700 cu ft per sec (Fig. 6(*a*)), and Siphon No. 2 discharging 350 cu ft per sec (see Fig. 6(*b*)). The flow in the open flume is from the spillway in the forebay and that in the unfilled barrel is from the free flow over its crest. The issuing jets look white and foamy but they are really crystal clear at the exit, under the curtain of water.

Range of Discharge.—The measurements of March 5, 1937, were made using a small quantity of waste water, all of which could be measured by passing it through the sluice-gate. From the rating curve (plotted from Table 2) and from these measurements the range of discharges, in cubic feet per second, was found to be:

Description	Siphon No. 1	Siphon No. 2
Maximum discharge for minimum forebay level without inhaling air	700	350
Minimum discharge	22	11
Minimum discharge expressed as a percentage of the maximum	3.1	3.1

Priming Head.—The head at which a siphon will prime is influenced by the rapidity of the rise of the forebay. When the forebay was raised very slowly

---

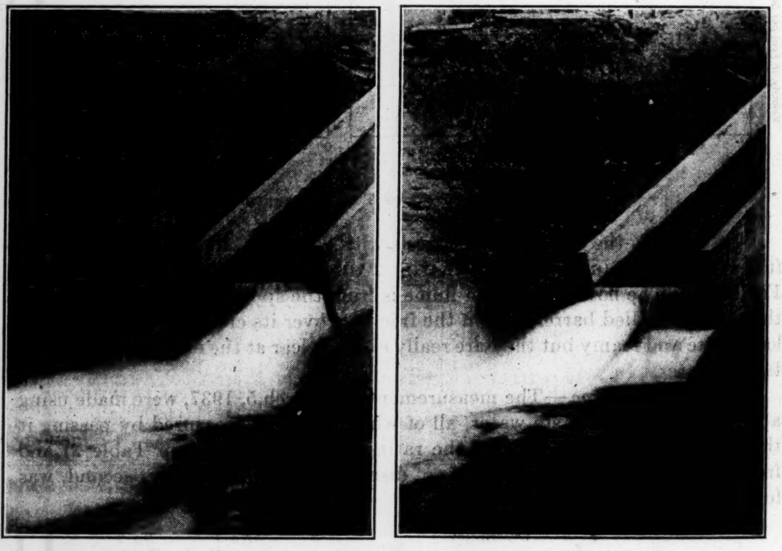
[3] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 991.

(say, 0.5 ft per hr, or less) the priming heads, in feet, were:

Description	Siphon No. 1	Siphon No. 2
Elevation of crest	595.10	595.00
Forebay level at time of priming	595.40	595.23
Priming head	0.30	0.23

TESTS BY PIEZOMETERS

As shown in Fig. 1 there are twelve sets of piezometer taps in each siphon. In making a test it was necessary first to establish a uniform flow with a stable canal and forebay regimen. By opening each cock in turn the pressure at each piezometer was indicated by the depression of the mercury (or water) column of a U-tube manometer. Oscillations were virtually eliminated by a damper attached to the manometer. Since all readings, except for the forebay and for Section *A*, were negative and since the tubes contained no water and the weight of the air column could be neglected, the elevation of the manometer was of no consequence.



(*a*) SIPHON NO. 1 (*b*) SIPHON NO. 2

FIG. 6.—CHARACTERISTICS OF FLOW WITH MAXIMUM DISCHARGE

Table 3 gives the list of piezometer tests made. The discharges indicated were taken from the rating curves as plotted from Table 2.

Fig. 7(*a*) gives the essential results of the tests for Siphon No. 1 running full. The vertical lines at the bottom give the negative pressure head, in feet of water. Each bar is the average of the pressure heads at the corresponding piezometer tap from Tests Nos. 4 and 11 in Table 3. The relation of the negative pressure head to that of one atmosphere is readily seen. The pressure heads are in the order of the numbering of the taps given in Fig. 1; that is, No. 1 in the left face, No. 2 in the crown, No. 3 in the right face, and No. 4 in the invert of the barrel, while facing the direction of flow.

TABLE 3.—LIST OF PIEZOMETER TESTS

* Except as noted, all tests were run on March 3, 4, and 5, 1937. † April 13, 1937. ‡ October 23, 1936.

Similarly Fig. 7(*b*) gives the results of the tests for Siphon No. 2 running full. The negative pressure heads, in feet of water, are the average of those for each tap in Tests Nos. 1, 2, and 10. The negative pressure heads from each tap in a section were averaged to obtain the average pressure head for that section. The average heads were then subtracted from the elevation of the center line of the barrel and 33 ft added to obtain absolute pressure heads from sea-level datum. These absolute pressure heads for each section are shown as circles on the drawings.

The elevation of the center line of the barrel has been plotted against its distance from the inlet, giving a developed profile of the siphon. The numbers indicate sections at which piezometer sets were installed.

Energy Line.—The discharge divided by the area gives the nominal mean velocity at each section, the velocity head of which, added to the absolute pressure, gives the points indicated by triangles. If the barrel were filled at all points by down-stream moving water, and if the piezometers correctly indicated the true pressures, and the average of all in one set indicated the correct pressure in that section, the triangles would define a line of energy for that particular discharge. That they do not truly define such a line is due to the barrel being partly occupied by eddies, by accelerating water, by entrained air greatly expanded under the nearly complete vacuum that obtains, and the inherent inaccuracies in determining mean pressures in a section by means of the four piezometers. The absolute pressure line has been drawn to fit the points as nearly as is consistent with fundamental principles. In general, it fits the observations.

It was impossible for the energy line to conform to the triangles throughout in view of the following principles that must obtain:

(*a*) It can never rise above its initial elevation but must continuously slope down stream because energy is being lost throughout the entire length of the barrel;

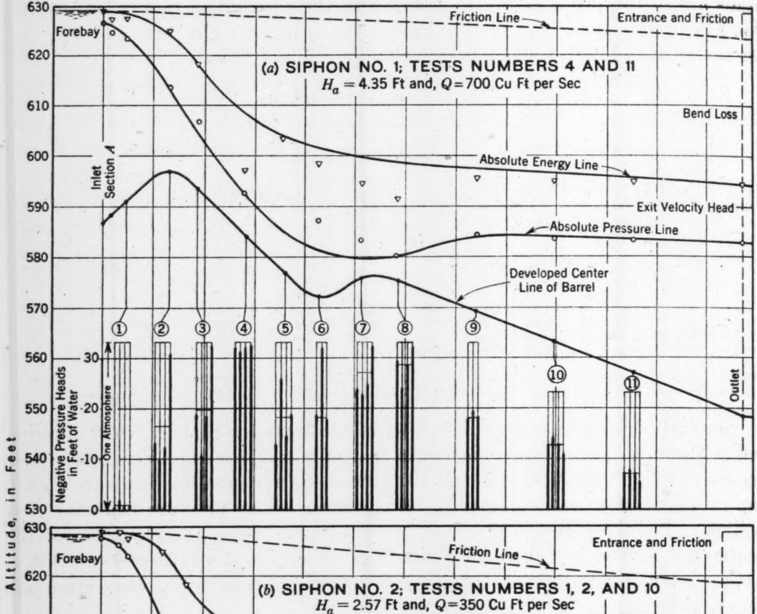

FIG. 7.—PRESSURE AND ENERGY GRADIENTS

(*b*) Its slope must never be less than that corresponding to the hydraulic friction for that discharge; and,

(*c*) Its distance from the pressure line must never be less than the velocity head corresponding to the mean velocity obtained by dividing discharge by barrel area.

Energy Losses.—The hydraulic losses are primarily of two kinds—hydraulic friction, and eddy and impact losses due to bends. The nominal friction losses were computed by the Kutter formula with $n = 0.013$, and by using the mean velocities obtained by dividing discharge of area.

The difference between the total loss and that due to entrance and friction is assigned to bends. There seems to be no doubt that the bend losses increase with the size of the barrel as there is more room in the larger barrels for eddying and spiral motion. They also are greatly affected by the distribution of velocities in the approach to the bends. Normally, the highest velocity and lowest pressure are on the inside of the bend. If the inside velocity is highest in the approach, however, the loss will be far greater than if the approach velocities are reversed.[4] Heretofore, all the experiments of flow around bends have been made with small conduits and under positive pressures. Large conduits under less than atmospheric pressures present an entirely new field of research that has scarcely been touched.

In the present case it will be noted that the difference in pressures between the concave and the convex sides of the summit bend amounted to almost 20 ft of water. (See Sections 2 and 3, Fig. 7.) Great inequality of velocities must result from the summit bend so that the approach conditions for the next bend become very complex and uncertain. To the loss in the summit bend must be added the effect of the discharge through the priming orifice joining the main stream at an angle.

In the present state of knowledge it is impossible to calculate or define the individual bend losses in these siphons. The total bend losses, however, can be determined approximately by the difference between total loss and calculated entrance and friction losses.

Table 4 gives the results of the tests for siphons running full, that is, not inhaling air. Explanation of the columns follows: Column (2) gives the average of the observed pressure heads at the four taps in each section (where the taps were plugged—Sections 6 and 9, Siphon No. 1—the average for Taps 1 and 3 —at the sides—was used); Columns (3) and (5) were taken from Table 1; Column (4) is the elevation of center line of the barrel, minus (or plus) the pressure head, plus 1 atmosphere (33 ft); Column (6) is the discharge divided by the area; Column (7) is the velocity head for velocities in Column (6); Column (8) contains the absolute pressure heads plus the velocity heads; Columns (9) and (10) are the adjusted values of the absolute pressure, and energy lines, read from the curves of Fig. 7; Column (11) is the difference between adjusted values of absolute pressure and energy lines; Column (12) gives the velocities corresponding to velocity heads of Column (11); Column (13) is the discharge divided by velocities of Column (12). (This represents the portion of the barrel filled by down-stream moving water, the remainder of the area being occupied by eddies); and Column (14) is the percentage of the total area occupied by eddies.

* Forebay. † Inlet. ‡ Outlet.

The discharges through the primer orifices were determined as illustrated for Siphon No. 1 as follows:

Forebay level	595.9
Pressure line at Section 1	590.4
Head on orifice (h), in feet	5.5
Velocity ($= 0.6 \sqrt{2 g h}$), in feet per second	11.2
Area of orifice, in square feet	2.35
Discharge, in cubic feet per second	26

The discharge through the Inlet, and Sections *A* and 1, therefore, was 674 cu ft per sec and, through the remainder of the barrel, 700 cu ft per sec.

Table 5 is a summary of the results for siphons when running full. It is to be noted that the total losses are greater in the larger barrel. The friction losses in the large siphon are only about one-half those of the smaller one, but the bend losses are 32% greater. The entrance losses were taken at two-tenths the velocity head at the Inlet Section.

TABLE 5.—SUMMARY OF TESTS FOR SIPHONS RUNNING FULL

Siphon No.:	Average of Tests Nos.:	HEAD LOSS DATA, IN FEET							VELOCITY, IN FEET PER SECOND				PERCENTAGE	
		Discharge, in cubic feet per second	Siphon head	Outlet velocity head	Total energy head	Entrance head	Friction head	Bend loss	Corresponding to siphon head	Actual mean outlet velocity	Summit mean velocity, Section 2	Corresponding to atmospheric head (33 ft)	Coefficient of discharge, outlet section	Efficiency of siphon
	(1)	(2)	(3)	(4)	(5)	(6)	(7)	(8)	(9)	(10)	(11)	(12)	(13)	(14)
1	4 and 11	700	45.9	11.3	34.6	0.4	5.1	29.1	54.3	27.0	27.0	46.0	50	59
2	1, 2, and 10	350	45.7	13.5	32.2	0.2	9.8	22.2	54.2	29.5	29.5	46.0	54	64

The coefficient of flow (Column (13), Table 5), is the ratio of the actual mean velocity at the outlet to the velocity corresponding to the siphon head. For these siphons running full this coefficient is 50% for the larger, and 54% for the smaller, barrel; that is, they actually discharge those percentages of the theoretical discharge for these particular siphons.

The efficiency of the siphon (see Column (14), Table 5) has been defined as the ratio of the actual mean velocity at the summit section to the velocity corresponding to a head of 1 atmosphere.[5] For these siphons, Siphon No. 1 has an efficiency of 59% and Siphon No. 2, an efficiency of 64%; that is, when running full they will discharge those percentages of the theoretical maximum that any siphon whatever could discharge.

Partial Discharges.—When the forebay level is too low to keep the priming orifice completely submerged, the siphons will inhale air, the volume depending on the forebay level. As they inhale air the discharge diminishes until it just equals the surplus inflow to the forebay. The pressures that exist within the barrels for partial discharges, were also determined.

Fig. 8(*a*) gives the result of Test No. 5 on Siphon No. 1 while discharging 300 cu ft per sec, or 43% of its maximum. The negative heads obtained from the piezometers are shown in the same manner as in Fig. 7. The pressure line shown is the normal pressure line (not absolute pressures). It coincides with the barrel at Section 9 showing that the barrel was aerated from the outlet to that point.

In similar manner Figs. 8(*b*) and 8(*c*) show the results for Tests Nos. 6 and 9 on Siphon No. 1 for 130 and 22 cu ft per sec, respectively. In these tests the

---

[5] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 1004.

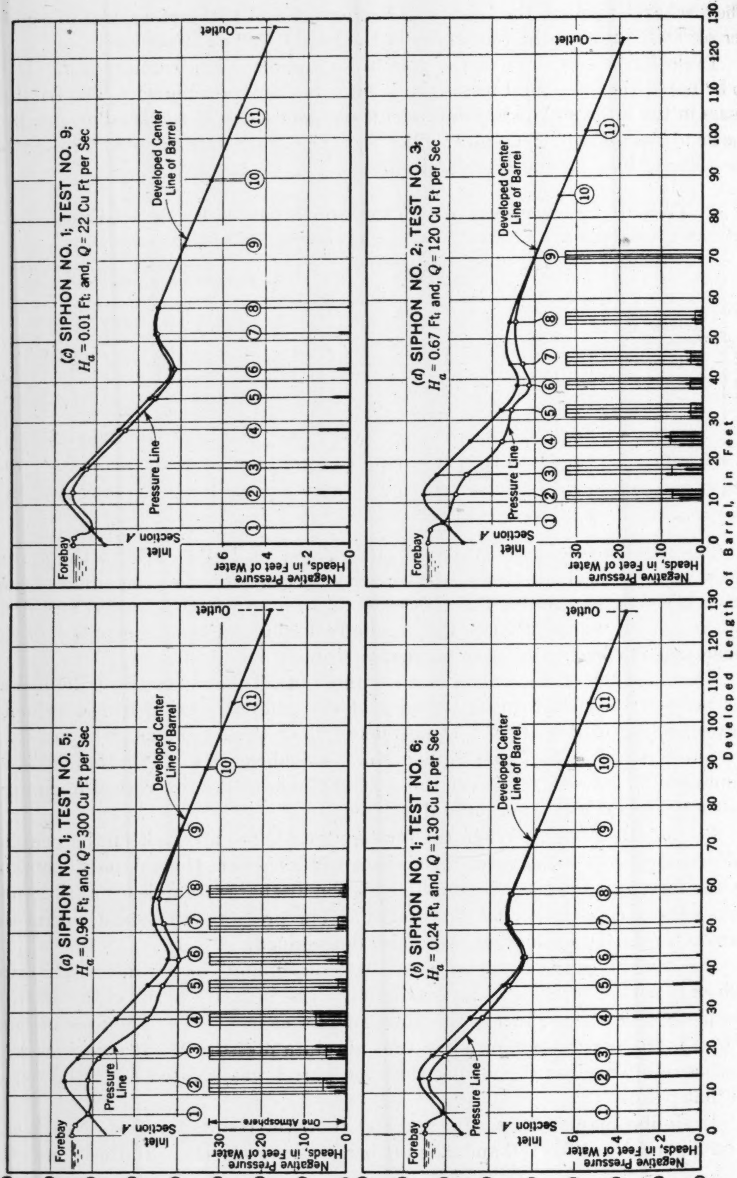

FIG. 8.—PRESSURE GRADIENTS

pressures in the piezometer manifolds, only, were observed. Negative pressures are indicated as far as Section 8 for both tests. The water flowed over the lower crest between Sections 7 and 8 without filling the barrel. This was equivalent to moving the siphon outlet to some point between Sections 7 and 8, materially reducing the siphon head below that for full flow.

Likewise, Fig. 8(*d*) shows the results of Test No. 3 on Siphon No. 2. As in the case of Siphon No. 1 the barrel was aerated from the outlet to Section 9.

CONCLUSIONS

The conclusion seems justified that the larger the barrel the greater will be the eddy losses and the less the efficiency. Efficiency, however, is only a minor consideration in the design of such siphons. The most important function is sensitiveness and range of discharge, features in which the Walterville siphons excel any others known to the writer.

One important function of the lower leg is to reduce the siphon head under partial discharges. As the discharge diminishes below the lower limit, Siphon No. 1 will cease first, and if the available discharge does not become less than 11 cu ft per sec, Siphon No. 2 will take it continuously. Thus, considered as a unit, the pair has a discharge range between 1 050 and 11 cu ft per sec, or 100% to 1 per cent. Siphons with such a range of discharge for continuous operation are truly remarkable and are believed to be unique in the history of such structures.

ACKNOWLEDGMENTS

Special credit is due to the Eugene (Ore.) Water Board, of which Mr. J. W. McArthur is Superintendent, for furnishing the facilities and assistance in making these tests. Their value looms large in the field of engineering research.

The details of the preliminary tests and of the design and construction were handled by Don Umphrey, Assistant Engineer, under the direction of Hugh P. Currin, Chief Electrical Engineer. The writer acted in an advisory capacity throughout and had charge of the final tests.

DISCUSSION

A. Griffin,[6] M. Am. Soc. C. E. (by letter).—Siphon regulators can be designed and built in many different ways and still perform their intended functions usefully. However, much remains to be learned as to the various factors affecting efficient design and most useful adaptation, and the author's paper is a valuable contribution to the subject.

It has been a debated subject whether a head greater than one atmosphere can be used effectively in a siphon regulator. W. P. Creager,[7] M. Am. Soc. C. E., has given a mathematical analysis to show that this is possible. The author indicates the same conclusion but does not specifically state it. His tests show that the siphon heads of nearly 46 ft are effectively used in the Walterville siphons. They closely approach the limit of head at Point 4. With a greater extension of the lower leg there would probably be a break in the water column near Point 4. With a shortening of the lower leg to give a head of one atmosphere, or less, there would be a reduction in coefficients of flow and siphon efficiency. The additional head greater than one atmosphere that can be used effectively is related to the energy losses and velocity changes below any point in the outlet leg selected for analysis.

The study of siphon behavior is important to the improvement of design and particularly to confident predetermination of capacity and performance. Violently destructive effects are not likely to be encountered, and there is usually ample opportunity to repair minor injury such as results from cavitation and wear. Nevertheless, it is desirable to reduce the destructive effects of turbulence and high velocities, and to gain the advantages of improved discharge efficiencies. This is especially true where large, or critical, heads are utilized in large-capacity siphons.

In any particular design siphon efficiency may properly be sacrificed in favor of some one or more desired characteristics, or to accommodate construction methods. Coefficient of flow and sensitivity or other desired characteristics are likely to be important points in the mind of a designer. Coefficients of flow will tend to be greater for smaller heads. Keeping in mind, also, that velocity varies as the square root of the head, it is evident that siphons utilizing comparatively low heads (even as low as 1 ft or 2 ft) may be employed usefully. A siphon with a head of 6 ft to 8 ft will probably discharge half as much as one with the maximum usable head.

A siphon is not likely to be clogged by any quantity of drift in pieces short enough to pass through it readily. The writer has seen a 4-ft by 4-ft siphon passing tangled masses of Russian thistles at an almost unbelievable rate, and has never seen a siphon clog. Two adjacent siphons, operating simultaneously, would be more likely to clog because of drift catching on the partition wall between them. This is a source of risk in any multiple-opening structure that is passing drift. It is very difficult to clog a single-opening structure.

[7] *Transactions*, Am. Soc. C. E., Vol. 85 (1922), p. 1122.

Perhaps the greatest and most common service that can be performed by a siphon regulator is as a strictly automatic regulator in which rôle it is almost perfect. For such use the writer suggests that it is most desirable to eliminate every form of manual control or adjustment. Of course, a siphon can also perform services in which manual control or adjustment is included as an essential feature.

It is desirable to emphasize to engineers the ease of design and construction and the wide variety of useful applications of the siphon regulator. In one case the writer built two inside forms, fixed the reinforcing in place, and then applied gunite. The completed siphons were hauled to location and hung in place over the top of a previously constructed concrete wall. The summit vertical dimension was 6 in., the width 3 ft, and the head about 9 ft. One siphon was given a sealing basin, the other discharged freely, and both gave the same satisfactory service. In 1938 a siphon of about 30 cu ft per sec capacity, utilizing about 6 ft of head, was welded together in the shop in sheet metal. It was installed by hanging it over a flash board in an irrigation-canal structure where it performs a very useful service. It is also hung to a screw lift so that the control elevation can be altered.

For most cases the siphon is effective from zero discharge to 100% of its capacity. When the flow is too small for the siphon to operate continuously it can still operate as an overflow spillway and intermittently as a siphon.

The writer likes the author's designation "siphon regulator." This is more adequately descriptive of its field of usefulness than the more limited term "siphon spillway." He disagrees with the term "primer." This opening is an air inlet to break siphonic action and thus would be better described as a "de-primer," or simply as an "air-inlet." At times it would be useful to have more information than is now available on the factors determining the minimum dimensions of the air-inlet necessary to interrupt siphonic action. It would be interesting to know whether any tests were made of the capped pipes at the summits, with the air-inlets ("primers") sealed.

The writer has never used a nappe aerator and would be interested in comments by the author as to conditions under which it is either necessary or desirable.

Engineers interested in siphon regulators should re-read the paper and discussions on this subject by the late George F. Stickney,[8] M. Am. Soc. C. E., published in 1922, and that by the author[9] published in 1934.

H. P. CURRIN,[10] ESQ., AND D. M. UMPHREY,[11] ESQ. (by letter).—Experience with the Leaburg siphons mentioned by the author indicated that these siphons would maintain flow down to about 25% of their capacity before breaking. At Leaburg there are five siphons rated at 500 cu ft per sec each, one rated at 250 cu ft per sec, and one at 100 cu ft per sec. It was decided that the Walterville siphons could be designed with fewer units of higher capacity. This would reduce the cost materially. A study was made at Leaburg[12] to determine the factors favoring the lower partial flows so as to take advantage of these points in the Walterville design. The backward sloping vertical legs at Leaburg are about 28 ft long. The lower leg is terminated about 25 ft from the end of the sealing pool section as contrasted with about 68 ft finally adopted for the Walterville installation.

With the Leaburg siphons running at full flow the water completely fills the outlet. With a small air admission at the primer the water falls away from the top of the outlet, venting back up the barrel and thus reducing the head on the siphon. The Walterville siphons were designed with a long lower leg to take advantage of this condition. Fig. 8 shows that this feature was justified. The shorter length above the sealing pool allows the siphon to prime faster, as less air must be removed to start siphonic action. These design features were favored by the configuration of the forebay wall and lower hillside at Walterville.

At Leaburg air is admitted under the primer into a narrow space. From that point it is drawn upward into a horizontal slot and discharged into the highest point of the upper crown where there is a very low absolute pressure when the siphon is running full and pressure is still considerably below that of the atmosphere at low partial flows. This results in a high velocity through the constricted passage behind the primer. Water is drawn several inches above the surface of the forebay into this passage, and the hydraulic conditions are such that there is an alternate passage of water and air through the priming passage in a series of gulps. When the siphon is running nearly full these gulps occur several times a second; but as the forebay falls and more air is admitted the period lengthens until the gulps occur about once a second when the siphon finally breaks at about 25% flow.

It was felt that this surging action had a tendency to break the siphon sooner than if the air were admitted steadily, and special attention was paid to eliminating this surge at Walterville, as far as possible. Fig. 1 shows how this was done. Air is admitted into each barrel as directly as possible from just above the forebay level. Although it was not possible to do away with the gulps entirely, they occur more frequently and are less violent than at Leaburg.

The horizontal primer lips shown in Fig. 1(*a*) were installed after the siphons had been in service long enough to show how far the surface drop-down curve, mentioned by the author, extended from the primer opening. Later these 12 in. lips were added.

Observations before and after adding the lips indicated that these devices caused Siphon No. 1 to run full 0.27 ft, and Siphon No. 2 to run 0.23 ft, below the forebay level necessary to shut off regulating air without them. Breaking and priming levels were affected very slightly, if at all.

An important element in the regulation of these siphons to low flows is the difference in elevation between the upper crest and the priming air intake. In each of the Walterville siphons, the top edge of the intake opening is set 0.2 ft above the corresponding crest.

---

[12] For illustrations, see *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 989.

In Table 2 it is shown that the lowest measured flows in both barrels occurred with the forebay at approximately 0.2 ft above the corresponding crest or at about the level of the lower edge of the priming lip. Although this head over the crest is not sufficient to re-establish siphonic action after the siphon has broken, it does tend to stabilize the lower flows which otherwise might be interrupted by surging in the siphon barrels. When these openings were lowered below their present position for testing the siphons were less stable at the lower flows and broke at a higher minimum discharge.

A 12-in. pipe was installed as a vent in the summit of the lower sealing curve in Siphon No. 1 and a 10-in. pipe in Siphon No. 2. It was thought that there might be some tendency of the water to cling to the tops of the long lower sections of the barrels at lower flows, and make it necessary to admit air through these vents by means of auxiliary regulating hoods in the forebay to vent the lower sections. Experience showed that this was not necessary, and the vents were closed by bolted flanges.

There has been some trouble with ice in the primers of the Leaburg siphons.[13] The high velocity and consequent sharp reduction of temperature of the admitted air in the constricted passages caused the primers to choke up with ice in a place very difficult to reach for clearing. Finally, 6-in. iron pipe nipples were cemented into holes drilled into the crowns of these siphons so that air could be admitted to break the siphons or to regulate their flow when the primers were closed by ice. This feature was also used at Walterville.

In the winter of 1936–1937, ice occurred at both Walterville and Leaburg. At Walterville some ice formed beneath the primer lips on both siphons, but it was easily removed. In a locality where ice is common it would probably be advantageous to install some heating device on the primer lips. These venting openings were very convenient while testing.

The author gives the priming level for both siphons with the forebay rising slowly. In 1936 a test was made to determine the effect, on the priming level, of raising the water quickly. The plant was shut down as fast as possible under normal operation. The forebay water raised at the rate of 0.38 ft per min. Both siphons primed together at Elevation 595.6 which is 0.2 ft above the normal priming level for Siphon No. 1, and 0.37 ft for Siphon No. 2.

In the Walterville design special care was taken to avoid air leakage around the adjustable primers. Smooth steel faces were used for all sliding joints, and jack bolts were provided to hold these joints together. It was found necessary to calk these joints to make them tight. Some form of gasket should have been included in this design.

The Walterville siphons vibrate to a certain extent at full flows. This is similar to the effect at Leaburg mentioned by the author[14] and is probably due to the same cause; that is, the water column separates and rejoins in the upper part of the vertical section.

Inspection of the Walterville siphons late in 1938 showed some slight erosion on the outside of the curves where water velocity is highest. Some erosion had also occurred in Siphon No. 2 on the inside of the upper curve, extending downward to the nappe aerator, or from Section 2 to Section 3 (see Fig. 9).

---

[13] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), p. 1011.

[14] *Loc. cit.*, p. 998.

The wear from Section 2 to Section 3 in Siphon No. 2 is in a place where absolute pressure is very low when the siphon is discharging the higher flow (see Fig. 7). This is also at a location where it was found very difficult to place concrete properly. A gravel pocket was found in this area after the inside form was removed during construction, and was filled by a surface patch. This patch shows very little wear.

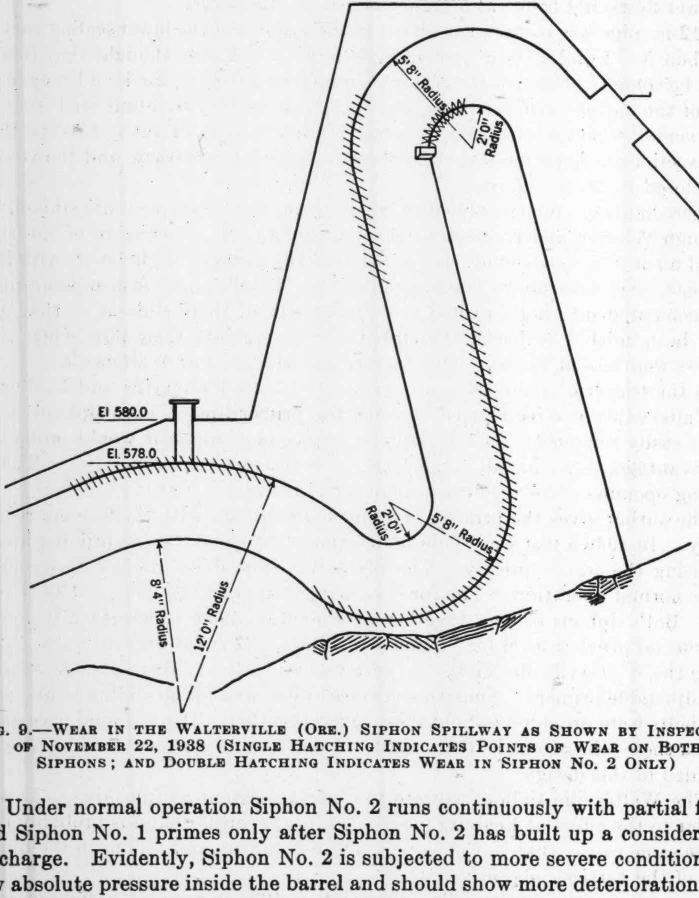

FIG. 9.—WEAR IN THE WALTERVILLE (ORE.) SIPHON SPILLWAY AS SHOWN BY INSPECTION OF NOVEMBER 22, 1938 (SINGLE HATCHING INDICATES POINTS OF WEAR ON BOTH SIPHONS; AND DOUBLE HATCHING INDICATES WEAR IN SIPHON NO. 2 ONLY)

Under normal operation Siphon No. 2 runs continuously with partial flow, and Siphon No. 1 primes only after Siphon No. 2 has built up a considerable discharge. Evidently, Siphon No. 2 is subjected to more severe conditions of low absolute pressure inside the barrel and should show more deterioration due to this condition than Siphon No. 1. The erosion in Siphon No. 2, Section 2 to Section 3, is no doubt due to cavitation.

Low absolute pressure occurs at all four piezometers at Section 4 at the higher flows. This section is in good condition in both siphons. Dense concrete is essential under conditions of this nature.

After eight years of experience with the Leaburg siphons and two years with those at Walterville, the writers feel that they would not hesitate to build other siphons for a similar purpose. It is felt that they are superior to any mechanical gate for this service. To quote from a report from the man in charge of operation "they are 'darn' good spillways."

T. J. Corwin, Jr.,[15] M. Am. Soc. C. E. (by letter).—The use of siphons for the control of water level, or for spillways, is of particular interest to the hydraulic engineer since a close regulation of water surface is possible. Mr. Stevens has presented a paper that represents a most thorough study on the action of siphons.

The design, arranged to have both a low head or high head on the siphon, is most unusual and can be used to advantage where enough head is available to make this layout possible. The adjustable primer can be used where unusual operating conditions will not permit a constant maximum water surface elevation.

Siphon spillways were selected to discharge excess flows occurring in the Tiger Creek conduit of the Mokelumne River power development of the Pacific Gas and Electric Company, in California, on the basis of reliability, close regulation of water surface, low cost, and freedom from maintenance. The conduit with a capacity of 550 cu ft per sec, completed in 1931, is about 20 miles long, of which 16 miles is concrete flume 14 ft wide and 7 ft deep. At several points along the conduit, feeder flumes or pipe lines pick up the flow of tributary streams. During certain seasons, the run-off from heavy rain or melting snow increases the flow from these feeder flumes to such an extent that the main flume would be overtopped unless protected by automatic spillways. Seven siphons were installed at points where feeders enter the conduit line, and tests were made on four, to check performance and to effect possible improvements in the design.

Fred C. Scobey, M. Am. Soc. C. E., A. W. Kidder, Assoc. M. Am. Soc. C. E., and the writer, made these tests in April, 1932.[16]

In so far as they bear upon the paper by Mr. Stevens the following conclusions from this test may be cited:

(1) The lower end of an inclined barrel should be either sealed or should have some vertical bends to cause the water to jet across the barrel;

(2) An auxiliary priming weir seems justified where the rise in water surface is limited (the depth required for priming was reduced about 2 in. when the auxiliary device was operating);

(3) Use of the lowest throat height consistent with good proportions, for the barrel, tends to decrease the head required for priming;

(4) The vacuum breaker pipes could be placed directly in front of the inlet rather than at the side since there is no appreciable surface disturbance when an enlarged inlet section is used;

(5) The air vent, which has an area of about 6% of the throat area, should be placed about 2 in. above the desired water surface elevation at which the

[15] Asst. Engr., Pacific Gas & Elec. Co., San Francisco, Calif.

[16] "Results of Tests on Siphon Spillways for Large Flumes," by A. W. Kidder and T. J. Corwin, *Engineering News-Record*, May 5, 1932, p. 649.

discharge should stop (the reason for this is that the siphon continues to operate at a partial discharge, sucking air and water through the vent until the water depth in the flume is correct for the setting of the throat of the siphon); and

(6) The use of more piezometer connections should be made for a complete study and the oscillation of the mercury columns should be damped. The rate of rise of the water surface should be controlled.

The operation of these siphons was free from objectionable vibration at all times, although the addition of sealing pools had been blamed for pulsations of some siphons. The pool had no apparent effect upon the discharge capacity.

Any designer contemplating the location of a siphon spillway in a conduit or small forebay must be sure that the water is free from entrapped air. The writer has had experience with a siphon located in a structure with two sources of water. It would prime with the water diverted from the stream but would fail to function when the excess water entered the structure in a turbulent manner from a pipe line.

Without a doubt, Mr. Stevens' test is the most thorough ever made and published. The energy line is of particular interest and shows where the major losses occur in the barrel, and the designer might be able to improve the coefficient of discharge by reducing the radius of curvation of the bends in the barrel.

It is interesting to note that the heads required for priming are about the same for the Tiger Creek and Walterville systems, and that the rate of rise in the water surface was found to influence the priming head in both cases. The apparent installation of trash-rack bars in front of the siphon shown in the Walterville structure might reduce the effectiveness of the siphon unless automatic rakes are provided to keep the racks clean.

HENRY R. KING,[17] ESQ. (by letter).—In 1933, Mr. Stevens called attention to the fact that "once it has started, the flow through any siphon may * * * diminish to a small part of its normal capacity without breaking of its siphonic action." Other writers have also discussed this phenomenon.

In its Southwest Sewage Treatment Works, the Sanitary District of Chicago, Ill., has three large siphon spillways which serve as excess flow and emergency by-passes. The spillways are designed to prime with water surfaces within 18 in. of the tops of channels and open tanks and to operate at any rate from zero to full discharge. Therefore, they may be classified as water-level regulators. The design was based on data obtained from small model tests made in 1935 to determine whether a siphon was suitable for this kind of service. The type of spillway tested (see Table 6) was found to be quite satisfactory. The overflow crest functioned as a weir until the flow was sufficient to raise the water surface to the bottom edge of the primer plate, at which elevation the level remained constant, the siphon inhaling air for the larger flows up to full discharge.

Table 6 gives the capacities, number of siphons, and dimensions for the large spillways at the Southwest Sewage Treatment Works. Each consists of a number of identical siphons in which all primer plates are set at the same elevation. The overflow crest is made of castings that can be raised for the installation of other castings under them—an essential provision in order to keep water levels down until after the addition of possible future stages in the sewage treatment process. The accessibility of the overflow crests makes this elevation adjustment possible. The overhang of the overflow castings is intended to serve as a nappe aerator.

	R_3	6 ft 0 in.	6 ft 0 in.	5 ft 6 in.

The wide variation of water depth in the discharge conduits of these spillways (see Table 6) will sometimes cause considerable depth of seal on the siphon outlets. Therefore, appreciable priming heads are required, and these determine the maximum water levels in the forebays. The lower edges of the primer plates have been set at approximately the priming head elevations. This means that when the water level is just below the primer plate, the free weir discharge over the siphon crest will be sufficient to provide a minimum water velocity, probably about 0.8 ft per sec, which will carry the entrained air down to the siphon outlet. For these spillways the discharge will reach about 5% of capacity before the water level rises to the primer plates, which means a lower relative range of siphonic discharge than was obtained for the Walterville siphons, with a minimum discharge of about 3% of capacity.

If the depth of seal on a siphon outlet is considerable, the ratio of the downward flow area to the width at the crest should not be too great if the priming head is to be limited; but if the depth of seal is only a few inches, as in the case of the Walterville siphons, priming heads are small and the ratio of flow area to crest width is probably not of much importance. The siphonic action, however, broke on the Walterville siphons at a water rate of about 0.9 cu ft per sec per sq ft of downward flow area.

When a siphon is inhaling air, it is functioning as an hydraulic air compressor. For this reason, experiments made by the writer on a small hydraulic air compressor, using a more elaborate type of water-level regulator, are of considerable interest in this connection.

The experimental set-up is shown in Fig. 10. Air entered the down-draft tube just below the siphon crest from several pipes, with perforated inverts, extending across the flow section. These pipes were supplied from an air chamber, under the crest, which was connected by pipe to the top of the water-level regulator, a chamber with open bottom partly submerged in the water in the headbox. The restricted area between the perforated pipe produced downward nozzle-like discharges into the surface of the water below, in the down-draft tube, entraining air which the water carried down into the separator chamber. When the perforated air pipes were supplied from the atmosphere, the water level in the headbox rose as the flow increased. To maintain a constant level in the headbox it was necessary to have, in the down-draft tube above the water surface, a partial vacuum varying with the flow. The water-level regulator produced this effect. The chamber inhaled air through a horizontal slot on one side. The water surface in the headbox remained level with the top of this air inlet for the full range of discharge used in the tests. The rise of the water inside the level-regulator chamber, due to the negative

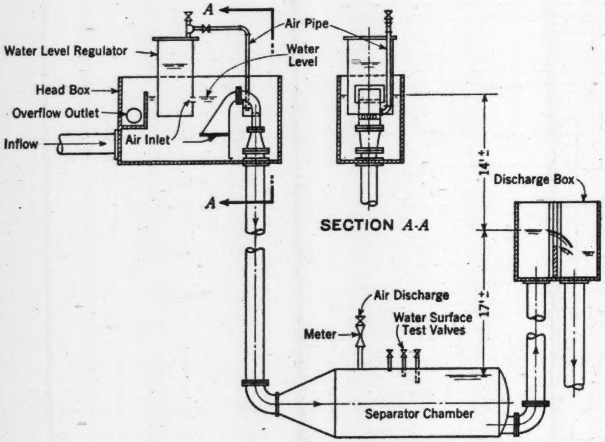

FIG. 10.—EXPERIMENTAL HYDRAULIC AIR COMPRESSOR

head transmitted from the down-draft tube of the compressor, could be limited by throttling the valve in the air line.

The tests indicated that, in order to avoid surging, the air inlet should be above the invert of the siphon crest and, also, high enough so that the rate of flow in the down-draft tube would increase to about 1.0 cu ft per sec per sq ft of area before the water level in the headbox rose to the top of the air inlet. Then, for the higher flows the water level remained unchanged. The maintenance of a constant water level at the entrance to an hydraulic air compressor is important, particularly if there is a varying flow and a relatively small working head.

The author's paper has genuine value. Presentation of the results of such careful and complete tests as those made on the large Walterville siphons is highly desirable. Much experimental work remains to be done before the engineer can compute with certainty the capacity of a siphon or similar conduit which includes bends of varying degree of curvature, closely spaced and, in some cases, with the final bend right at the outlet.

J. C. STEVENS,[18] M. AM. SOC. C. E. (by letter).—Mr. Griffin raises the question of the total head under which a siphon may operate. The fundamental principles of siphon behavior are fully set forth in the writer's paper[19] on the Leaburg siphons, wherein it was shown that a head considerably in excess of one atmosphere may be utilized. A straight pipe between forebay and tail-water will discharge more than a siphon of the same size, but its action is not automatic without the use of automatic gates. By placing a part of the pipe above the normal hydraulic grade (not the absolute pressure line) it becomes a siphon, and no gates or valves are required. The advantage of a siphon over an ordinary connecting pipe lies principally, if not solely, in its automatic functioning without moving parts.

The maximum possible discharge that any siphon can have will occur when the velocity head at the summit equals one atmosphere. This is an ideal condition, however, that cannot be realized for two reasons: First, some of the atmospheric head is consumed in entrance and friction losses from the inlet to the summit; and second, the continuity equation $Q = AV$ (in which A is the cross sectional area of the siphon barrel) does not hold for such high velocities around bends. The result is that the maximum velocity occurs at some point below the summit where a part of the siphon barrel is occupied by eddies. In the Walterville and Leaburg siphons, under full discharge, the points of maximum velocity were down stream of the summit, as shown in Table 7.

Mr. Creager's discussion of Mr. Stickney's paper, to which Mr. Griffin refers,[7] presents the analysis of siphon behavior current at that time but which is now known to be faulty in some particulars. Mr. Creager states "The pipe will always remain full if it is tight and the hydraulic grade line, as used in Fig. 1 [see Fig. 11(*a*)], is above the top of the pipe at all points." Presumably, Mr. Creager meant "full of down stream flowing water." The experiments on the Leaburg and Walterville siphons have demonstrated that this is not necessarily true. Mr. Creager's proof that the siphon can discharge under heads greater than one atmosphere is also faulty as will be seen readily from Fig. 11(*b*).[20] Suppose the siphon did not discharge horizontally but continued sloping downward to a pool. Both hydraulic grade lines shown in Fig. 11(*b*) would intersect the lower leg throughout its entire length. Now suppose that the horizontal outlet were turned through 180°, as actually occurs in the siphon of the Southwest Sewage Treatment Works, illustrated in Mr. King's discussion (see Table 6), wherein the tail-water is vertically beneath the head-water. The hydraulic grade line would not touch the siphon barrel no matter how widely the head and tail-water were separated, and according to Mr. Creager's criterion the siphon could then operate under an infinite head.

FIG. 11.—DISCUSSION OF SIPHON SPILLWAYS

---

[20] *Transactions*, Am. Soc. C. E., Vol. 85 (1922), Fig. 16, p. 1123.

The fault lies in not developing the siphon barrel as was done by the writer in Figs. 7 and 8 wherein the elevation of the siphon barrel is plotted against its length along the barrel from the inlet. When this is done Mr. Creager's criterion holds. Of course, it is conceivably possible to build a siphon with any head whatsoever—say, several hundred feet; but, wherever the absolute pressure line intersects the siphon barrel, developed as previously indicated, the absolute pressure in the space between such intersections will be equivalent to the vapor pressure of the water—virtually a vacuum—and that part of the barrel will be useless as a siphon. This condition is illustrated in the writer's paper "On the Behavior of Siphons."[21]

Mr. Griffin objects to the term "primer" and suggests "air inlet." The facts are that when siphonic action starts it is caused by shutting off the air to this "air inlet"; the device, therefore, does act as a true "primer." He also asks for comments on the "nappe aerator," and under what conditions it is necessary. Whenever the sheet of water flowing over the crest is to fall free from the invert across the siphon barrel to facilitate exhaustion of the air, such an aerator will aid in freeing the nappe. In Fig. 1 note that the lower legs of the siphons slope toward the head-water to aid in air exhaustion by this method.

Messrs. Currin and Umphrey have mentioned the advantages of the backward sloping short lower leg in quick priming. They have also added some valuable data on cavitation within the barrel. The pitting of concrete is minor and is readily repaired at intervals of 3 to 5 yr.

Mr. Corwin mentions the question of racks. This is an important feature in siphon design. At Walterville and Leaburg the racks were spaced 6 in. clear, the object being merely to prevent anything from sticking in the primers. Racks spaced closer than this are not necessary and would give considerable trouble with frazil ice.

The large-capacity siphons described by Mr. King are quite interesting. He does not give the priming head but intimates that it is considerable. The forebay must rise 0.75 ft above the crest before it closes the primer. The writer believes that if greater sensitiveness is desired it can be secured by reconstructing the primer. Doubtless the design of the primer adopted was based on the model tests mentioned by Mr. King. The writer seriously questions the value of model tests for this purpose. The laws of similitude do not cover the case of less than atmospheric pressures unless the model tests are conducted within a chamber in which the atmospheric pressure can be reduced to correspond to the model scale. Moreover, surface tension becomes important in small models but may be safely neglected in the prototype.

The provision for raising the crest at some future time is a novel and practicable idea. Apparently the crest could be raised at least a foot without throttling the flow.

In indicating the range of discharge for the Walterville siphons, the free flow over the crests before priming was not considered. When that is taken into account the siphon practically discharges at any point from 0 to 100% of its flowing-full capacity, as Mr. King states is the case with the siphons illustrated by him.

---

[21] *Transactions*, Am. Soc. C. E., Vol. 99 (1934), left-hand sketch of Fig. 10, p. 1000.

Fig. 12 shows a discharge curve for Walterville Siphon No. 1 in terms of forebay elevation. The free discharge over the crest is shown to a more extended scale than for the remaining flows. As the forebay rises and falls the discharge will follow the cycle indicated by the arrows.

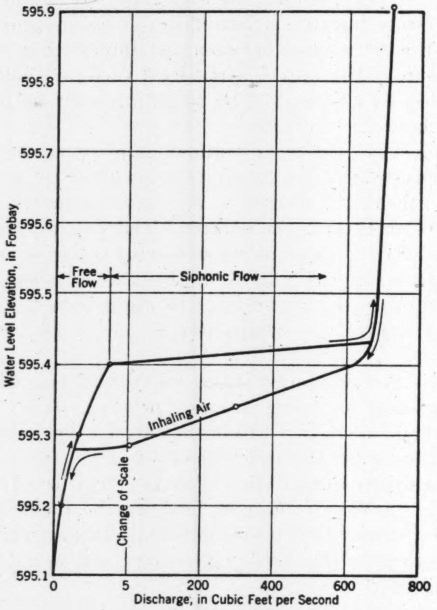

FIG. 12

None of those who discussed the paper mentioned the use of an energy coefficient in determining the energy line of Figs. 7 and 8. Where the mean velocity, Q/A, is used the energy head may be expressed correctly by

$$h_e = \frac{C_e V^2}{2g} \qquad (1)$$

as has been shown by Morrough P. O'Brien, M. Am. Soc. C. E., and Joe W. Johnson, Assoc. M. Am. Soc. C. E.[22] The coefficient C_e is a measure of the velocity distribution within the siphon barrel—the greater the velocity distortion the higher the coefficient. It can never be negative. Since the velocity distribution was unknown this coefficient could not be computed in advance. Through the writer's method of adjusting the energy line, however, the value of these coefficients can be determined from Table 4. It is the ratio of the adjusted velocity heads of Column (11) to the velocity heads in Column (7). The values of this coefficient are thus seen to vary between 1.00 and 1.78 for Siphon No. 1 and between 1.00 and 1.95 for Siphon No. 2. These high values are not surprising when the disturbances of the bends are taken into account.

FRONTIERS OF ENGINEERING

ADDRESS AT THE ANNUAL CONVENTION, SAN FRANCISCO, CALIFORNIA, JULY 26, 1939

By Donald H. Sawyer,[1] President, Am. Soc. C. E.

Progress, although viewed in some circles of thought as a glorious symbol of more speed and bigger machines and in others as a covering for inhuman materialism, is in reality a conception embodying the most profound and the most potent ideas at work in the Modern Age. It is, at the same time, an interpretation of the long history of mankind and a philosophy of action in this world of bewildering choices. It gives a clue of meaning to the rise of civilization out of the crudities of primitive barbarism and offers a guide to the immense, impending future.

Progress or Stagnation?

In essence, the idea of progress belongs to present times for it was not known to the ancients and to the thinkers of the Middle Ages. It has become more than a theory. It has achievements to its credit on every hand—disease and pain alleviated, the span of life lengthened, famine made obsolete, comforts and conveniences established, and improvements developed in every line of trade that points toward the goal of increasing perfection. Of course, progress is born of faith—faith that the world, as Emerson stated, "is all gates, all opportunities, strings of tension to be struck." This faith confronts obstacles with assurance; where the pessimists face the worst, it proposes a search for the best. To suffering, ignorance, and fear, which drive the timid to the Nirvana of doubt and oblivion, this faith calls to action, to research, to planning, to conquest, to a naked avowal in these United States that the earth is to be made submissive to the secure welfare and delight of them that dwell thereon.

About 1787 Mr. Tench Coxe of Philadelphia, Pa., opined as follows:

> "The population of Pennsylvania appears to have increased in 23 years, nearly in the proportion of 39 to 91, though the whole term of a revolutionary and invasive war of seven years was included. This considerably exceeds Dr. Franklin's estimate of doubling in twenty years. Now that all New England is full, except Maine and Vermont, the contiguous states

---

[1] Chf., Section of Space Control; U. S. Treasury Dept., Procurement Div., Washington, D. C.

of New Jersey and Delaware are overstocked, and Maryland nearly so; and above all, now that Europe is full and much disturbed, a curious rapidity of population is to be expected in a state with so much unimproved land, disposition and capacity for manufacturers, wealth, foreign intercourse, energy and enterprise as Pennsylvania."

In 1843 a report of the United States Patent Office contained the statement that "the advancement of the arts from year to year taxes our credulity and seems to presage the arrival of that period when human improvements must end." These incidents occurred fifty-six years apart and in the interim there probably were many other forecasts by reputable characters voicing their beliefs that the incipient American spirit of creative genius had about run its course. After the interval of a century the same foreboding is abroad in the land—in very recent years we have listened to a new slogan to the effect that there are no more frontiers in America.

When trite phrases that catch the public fancy emanate from authoritative sources, it is quite natural that credence be given to the philosophy of the remarks. But examples such as these throw a "wet blanket" over the enthusiasm of those whose part in American advancement has been the production of better things for life and industry.

AMAZING ADVANCES IN TRANSPORTATION

It is quite true that migration from the Eastern shore lines of America to the Pacific Coast has been completed, that the intervening spaces have been adapted to agriculture and industry in large part. But this does not imply that all of the open spaces are productively at work, and especially it does not mean that Americans, most favored people in the world, are satisfied with their present surroundings and facilities.

The discovery of gold in California emphasized the acute need for railroads to cross the continent. Enormous distances and natural resources spurred the inventors and engineers to develop the railway—and to-day the United States boasts the greatest network of railroads of any country in the world.

Where once it took months for a slow-moving animal-drawn caravan to make the journey from the Mississippi River to the West Coast, there followed railroad trains which cut the time of travel across the country to two weeks, and more recently to two and one-half days. Airplanes have reduced their schedules to fifteen hours, while passenger automobiles can make the journey comfortably in a week.

Tremendous strides have been made since the gold rush to California. Years ago it took a vessel months to circle the Horn, whereas to-day fast steamships complete the journey from coast to coast, through the Panama Canal, in two weeks. The engineer has justly taken credit for all these advancements in science.

If it be true that the territorial frontiers have been surmounted, can it be said that the frontiers of technical advancement have likewise reached their highest culmination? If the answer to this question is affirmative or is couched in doubtful language, it must be concluded that America must accommodate itself to tremendous changes. But the answer is "no"; and although fundamental things have been provided for a higher civilization there will be no pause in the thinking and accomplishments of the technicians of this nation for years to come.

The engineer has not yet reached his frontier nor has he even come in sight of it. Habits of mind, clarity of thinking, trust in his own self-assurance, opportunity for public service—all these constitute mental and physical resources which show no indication of exhaustion but rather have provided him with better tools that permit him to perform even greater deeds for mankind.

COMBINATION OF EFFORTS

It is well, in contemplating the equipment of the engineer, to recognize the mental and physical forces which join hands with him in developing his enterprises. Roughly his colleagues are men and materials. These may be grouped into the categories of finance, design and supervision, and construction.

In finance are included those elements that contribute money in its various forms in order that labor and materials may be joined into lasting works.

By design and supervision is meant the process wherein the engineer, the architect, and all other technical men whose ingenuity permits them to foresee what is needed, reduce their conceptions to drawings and specifications; and later watch the unfolding of their plans in the field, to the end that their creations may be honestly and efficiently brought into being.

Finally, construction comprehends the manipulation of men and materials. Millions of people have given the best that is in them to this great productive development. They not only labor at the site of the undertaking but are engaged in producing raw materials, in following these through the fabrication stages in the factories, and in expediting their transportation to the location of the job. Through a long sequence of complex operations, they trace the ore and the timber from its natural habitat to its final placement in a completed structure.

This picture of the construction industry, sketchily drawn, is so commonplace in American life that it fails to receive the credit which is its due. This business adds to the permanent wealth of the country and is second only to agriculture in its vast volume. It gives a livelihood to millions and constitutes the greatest single force that has made the United States the leader of the world in providing necessities, conveniences, and luxuries for its people.

SETBACK OF INDUSTRY CREATES UNTOLD HARDSHIP

This great army of men has been steadily advancing for a hundred years. Its progress continued until the early 1930's, when something occurred that interrupted its forward movement. Since then this great part of American business and life has staggered in an effort to recover its lost ground.

Many tonics, many medicines and panaceas, and great profusions of words have been administered in valiant attempts toward resuscitation. In spite of all these efforts the industry is to-day far below its legitimate level. Graphically, in Fig. 1, a diagram is displayed[2] which indicates more forcefully than words the historical rise and decline of this great industry.

---

[2] From "Construction Activity in the U. S., 1915–37"; publication of the U. S. Department of Commerce.

While credit must be given to the engineer for the benefits he has conferred on modern life, it must be realized at the same time that in gaining the high position which he enjoys to-day he has carried along with him a section of humanity for which he must stand sponsor if he remains true to his faith. No one can accurately estimate how many men look to the construction industry for their livelihood but the best available figures range from 5 000 000 to 8 000 000 human beings. The tragic drop in the volume of construction has turned a considerable percentage of these people out on the streets and put them on relief rolls. Possibly the greatest portion of public charges to-day (1939) were formerly engaged in the pursuits of the engineer. To his responsibility must also be added a part of the increased population year after year, together with men displaced due to the introduction of labor saving devices.

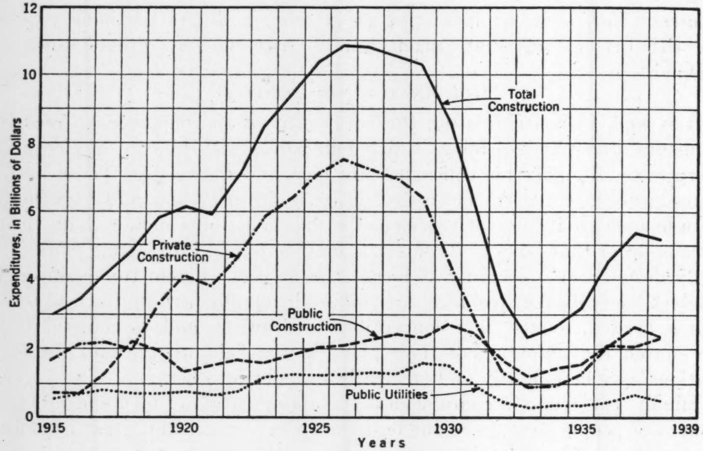

FIG. 1

CHALLENGE TO ENGINEERING ABILITY

And so the technical man—qualified as he is and distinguished in his trustworthiness, his thinking, and his zeal for public service—must pick up this load if the United States is to have substantial recovery. So long had he been ingrained with the idea of a market for his creations that he was not prepared for the shock of the depression. He floundered, became discouraged, accepted the fallacy that America had no more frontiers, and somewhat succumbed to an undefined bewilderment. He must shake off his apathy, and his recourse to temporary alternatives. He must revive his clear thinking, reassert his courage and inventive genius, and again take up the burden that properly belongs to him as his full share of American industry.

To do so involves no great departure from the engineer's former habits of mind. The problem constitutes a challenge to his talents that promises a greater reward for public service than has ever before presented itself to him. If he will not reassert himself, he and his industry must continue to suffer; but if he will go forward he will do for America greater things than have been accomplished in the past and will play his full part in bringing the nation out of its difficulties.

But, why pick on the engineer and charge him with leadership in such a program? The answer is that he has always been in the key position of the construction industry. His have been the ideas, his the means by which these plans can be brought to reality including, of course, financing and construction. He has been the motivating force of the industry, the man who has been sought by those who desire to create physical things. He has been the captain of the construction team and it is his function to call the signals, to direct the plays, along lines that give assurance of success.

Presumably most people will agree with these observations regarding the desperate condition of the construction industry, the welfare of the men for whom the industry stands responsible, and the faith of the engineer in his calling. If these things be taken as true it remains to discuss what means should be employed to revive the business that has engaged his talents.

CREATIVE IMPROVEMENTS

There seem to be no short cuts to a substantial return of the former volume of construction. No miracle man is in sight who can lead America out of the present wilderness. The road back must be along conventional lines where experience has demonstrated assurance of success, and must include hard work, good judgment, and the revitalization of creative genius. Nor is the struggle a one-man job for the Civil Engineer; rather it must be attained by team-work among all elements of the construction business. Leadership may well be, and should be, exercised by the technical forces. All those others whose livelihoods depend largely on construction must collaborate.

Eternal change has been the life blood of the industry, whose slogan has been, "Don't do to-day what you did yesterday; do something better." Indicative of the striking changes of the last half century are many available illustrations, all of which emphasize the trite saying, "Off with the old, on with the new." Few facilities and improvements in America disappear because their usefulness has passed; most of them are displaced because something better has been introduced that promises higher service.

The construction industry has been energetic during the last few years of the depression in producing machinery, equipment, and facilities to lower the cost of production—labor saving devices. The type of inventive mind that has brought these things into being apparently has been insensible to the proper planning and creating of things that the public will buy.

SUCCESS IN OTHER FIELDS

Of course, there are bright spots in American industrial life where creative genius has maintained the pace of former years and has not faltered. A prime example of this is the chemical industry. This sector of American business has been alive in its pursuit of new products that a waiting public might acquire. Millions of dollars have been invested every year in research, other millions have been invested in new factories and improved equipment that bring into being the ideas which have been germinated. Brand new creations have appeared in recent years that were never thought of before and eager buyers have absorbed these products. The public, however, would not know of these productions were it not for the good judgment and funds which have been invested in promoting and marketing them. This experience indicates that genius has not disappeared, that money is available, and that people will buy something new when it is better than the old.

The thrilling story of the advancement of chemistry has its parallel in the by-gone days of the construction industry. But vastly greater than was the case with chemistry are the phenomenal opportunities for construction that lie ahead. The creation of these opportunities calls for greater emphasis on investigation, discovery, and invention than has been devoted to these purposes in former years.

A few developments of contemporary significance can be mentioned in the engineering field. Air-conditioning of our buildings was launched as an adventure a few years ago and to-day its application is found in a wide variety of structures and railway accommodations. What its ultimate future may be cannot be predicted, but with money and human talent allocated to its development it gives promise of becoming a means of permanent and expanding service to mankind.

The latter-day adaptation of internal combustion motors to railway transportation with lighter and more modernized equipment forecasts a trend that with the greater improvements bound to follow is entirely revolutionizing travel by rail. These examples may be largely multiplied as showing the creative contributions to American technical life.

A PROGRAM

Greater sums must be set aside for research; and capable staffs must be formed to develop new ideas which show promise for commercial use. This money should be allocated to laboratories and research institutions, as well as to manufacturers and technicians, wherever the assurance seems justified that its distribution will lead to betterments. There are countless numbers of men who have within their minds convictions which, to bring into being, would require funds. Some efforts will succeed and others will fail but in the aggregate the investment will prove its value. Manufacturers and many other institutions of great variety foresee innovations which require expenditures for commercialization. All of these budding ideas should be supported, when seemingly of worth, to the end that the resources latent in the American mind may be reawakened. For such a program a sizable sum of money would be needed and there is doubt if it could be accumulated in a short time within the construction industry, where the units are moderately small and the collection of a large amount presents many difficulties. Since this is true, the Federal Government, if properly advised of the purposes to which an appropriation would be devoted and of the reliable auspices under which the spending would be conducted, might give consideration to legislation that would motivate a program. The unified support of the industry should be behind a program of this nature.

The creation of new facilities is the target at which to shoot. Americans have an appetite for the best that life affords. As a companion movement, therefore, the industry must devise all proper means to acquaint the public with that which it has to offer and must do so by more thoroughgoing practices than have been in vogue in the past. When this great machine is in working order, with money, man-power and materials, and with a public eager for the best, the sale of its wares whenever properly presented can be expected.

The American Society of Civil Engineers is so organized as to give at least initial momentum to such a procedure. Its twelve technical divisions speak for specialized engineering, embracing city planning, construction, engineering economics, highways, hydraulics, irrigation, power, sanitation, soil mechanics and foundations, structures, surveying and mapping, and water-ways. These groups can well examine and explore this problem and they can become the motivating forces in this program to restore construction. From such centers the ideas and recommendations can be communicated to other elements of the industry, which might bring about a larger conference with a concord of views. Out of a meeting that speaks for all elements might come a highly qualified committee to give direction to the formulation of future plans.

CONSTRUCTION PROBLEMS AND CONSTRUCTION OPPORTUNITIES

Let us restate the condition and future of the construction industry:

This business has assimilated a very significant portion of the population in its advancement in the last century;

It has won its way by the introduction and execution of improvements startling in their benefits to humanity;

The depression has pushed the volume of construction down to a fraction of its former level and has forced its men into idleness and on relief;

The industry cannot escape its responsibility in taking the leadership and overcoming the situation as it exists to-day—to do this it must revert to the methods which gave it success in the past, namely, the display of creative and organizing ability;

The time has come for construction to reassert itself, to shoulder its responsibility—this means a co-operative movement founded on hard work and sane thinking of its component groups.

If this business will shake off its lethargy, re-establish its belief in itself, and work industriously, engineers can face the future with a revived confidence and with convictions; they can pick up their load and quickly start American business on the up-grade.

American ingenuity has not finished its course.

The fertility of the technical mind is not exhausted.

The frontiers of engineering have not been reached!

Paper No. 2055

INTERSTATE WATER PROBLEMS

FINAL REPORT OF THE COMMITTEE OF THE IRRIGATION DIVISION ON INTERSTATE WATER RIGHTS

Introduction

The Committee published progress reports in 1927, 1928, and 1930.[1] Much of the interstate litigation and negotiations for interstate compacts, covering the use of waters of interstate streams, has occurred since the latter date. Vital questions of Federal *versus* State jurisdiction have arisen, largely because of increased activities of various Federal agencies as a result of legislation enacted by the Congress since 1932, in the interest of industrial recovery and conservation of the natural resources of the nation.

In connection with the important subject of interstate water with which this Committee is concerned, U. S. Federal and Supreme Court decisions, and papers written by various Federal, State, legal, and engineering authorities, have been reviewed by this Committee and freely drawn upon in the preparation of this report, with the view of bringing up to date a compilation of the history covering compacts, litigation, and Court decisions concerning the use of the waters of interstate streams.

In its desire to make this report as inclusive as possible, certain phases of the work were allocated to various members of the Committee, the special topics involving review and research of current engineering literature, Federal Court digests, reports by various Federal agencies, such as the Water Resources Committee of the National Resources Committee, the U. S. Bureau of Reclamation, Federal Power Commission, American Bar Association,[2] Federal legislation affecting interstate and international streams, the Rocky Mountain Law Review, Harvard Law Review,[3] Yale Law Journal, New Jersey Law Review, and University of Pennsylvania Law Review. In addition, questionnaires were sent to the Attorneys General and State Engineers, or other water officials, of all the forty-eight States, requesting data concerning interstate litigation pending or concluded, or negotiations for, or compacts which have been concluded between States, covering the use of the waters of interstate streams. The Committee acknowledges the sources of much of the material used herein and desires to express its thanks and appreciation for such use, and for the valuable assistance rendered by these various agencies. The Chairman also desires especially to thank J. B. McCormick, Dean of the Law School, University of Arizona, Tucson, Ariz.; William R. Kelly, Attorney at Law, Greeley, Colo.; and Wells Hutchins, Irrigation Economist, Bureau of Agricultural Engineering, Berkeley, Calif., for reviewing the report of the Committee, and the Honorable Ralph L. Carr, who prepared that part of the report covering the litigation over the La Plata River Interstate Compact.

[3] "Interstate Rights in Interstate Streams in the Arid West," by L. Ward Bannister, Denver, Colo., 36 *Harvard Law Review*, 960 (1923).

The Committee does not conceive it to be its function to express any particular view, or to draw conclusions with respect to any of the matters discussed herein, with which various individuals may disagree. It has attempted to limit its report to a compilation of the history of interstate litigation and compacts covering the important subject of interstate waters, together with a brief digest thereof, and the views of various commentators thereon.

Problems Related to Interstate Waters.—Interstate water problems exist on almost every interstate stream of the nation, or are potential sources of interstate controversies. They are becoming more complicated and more difficult to solve as the need and demand for water increases. In recent years, public attention has been directed as never before toward the water problems of the nation. Withering droughts and devastating dust storms in the arid regions of the West, wide-spread soil erosion, record-breaking floods, and receding water-tables—with increasing needs for ample and stabilized water supplies for great centers of population and industrial areas, and the need for mitigating the dire effects of stream pollution—have caused grave alarm throughout the nation. No doubt, these conditions arose because there has been a protracted cycle of deficient precipitation that culminated, generally throughout the West, in the extreme low of 1934. The gradual increase in population and expansion of irrigated areas in the arid West have likewise made heavy and increasing demands upon the limited water supplies available to those areas, the future development of which must of necessity be restricted to the ultimate consumptive uses of such supplies.

In a humid region, except for comparatively limited demands for domestic, industrial, and sanitary uses, waters are more often an agent of destruction than a blessing, and place a heavy financial drain upon the resources of communities, States, and the nation, for their regulation and disposal. Such demands, however, have not raised problems of an interstate nature, as have the more vital needs for domestic and sanitary purposes, and for the production of food supplies in the arid West. These latter problems may be considered, in general, to be of more local than national concern. They have forced communities, centers of population, and even States, to search beyond their confines for water supplies to meet their growing necessities. As a result, the people dependent upon the waters of a stream view with distrust any attempts to divert a portion of its waters to another water-shed or basin, and a State is even more jealous of the water supplies that originate within its boundaries. Its people are inclined to insist upon their right to the unrestricted use of its waters, not only for present, but for all future requirements, irrespective of the needs of the citizens of another State.

In the arid West, practically all development and progress is dependent upon a consumptive use of its water supplies. Based upon the doctrine of prior beneficial use, earlier development in a lower State has tended to place heavy restrictions upon uses of water from an interstate stream by an upper State. This condition has brought on long and costly litigation between States in their efforts to protect what they conceive to be the legitimate interests and the rights of their citizens.

The Constitution of the United States, as drafted in 1787, represented a bold and original effort to create a political system in which the cumulative advantages of a large National State could be established, with full opportunity for political development and expression, through the autonomy of member States. That these member States were conscientious and jealous of their individual personalities and interests is amply demonstrated, not only by colonial history, but also by that of the Confederation. The Constitution of the United States is in the nature of a contract between the States, whereby specified and limited functions of Government are delegated by the States to the United States of America by assignment of certain inherent sovereign powers and duties to the Congress, the President, and the Supreme Court.

Article I of the Constitution, in which powers are conferred upon Congress, also includes Article X of the Amendments, which places certain restrictions upon the exercise of these powers. Further reservations were attached in earlier years by Articles I to X, in the form of amendments to the original Constitution. Article I, in which powers are conferred and restrictions placed upon the Congress, also places certain restrictions upon the several States, among which is the following: "No State shall, without the consent of Congress, * * * enter into agreement or compact with another State, or with a foreign power * * *." It has been assumed that this part of Section 10 of Article I of the Constitution is to be interpreted as actually permitting or authorizing agreements between two or more States with the consent of Congress.

Under the general conception, the Federal Government's authority in regard to waters is limited to that required for the regulation and control of the waters of an interstate stream, in the interest of navigation and national defense, and also to the consummation of international treaties. It is also possible that, with respect to certain of the natural water supplies of the Western States, the Federal Government may have rights, superior to those claimed by the States, under its powers to enter into treaty obligations with Indian tribes, during the territorial status of the land, and with bordering foreign countries. In the Western States, however, there is a disposition to question this purported authority of the Federal Government with respect to Indian tribes. In general, when this question has arisen between Federal and State authorities, the conflicting viewpoints have been adjusted amicably without the necessity for a final determination of the principle by the Courts. There has been a tendency for various agencies of the Federal Government to extend their authority over the waters of navigable streams, or even tributaries thereof, in the administration of the asserted functions of their respective offices, as a result of various Federal Laws based upon the constitutional power of the Federal Government to control navigable waters.

Doctrines of Water Law.—The doctrines or principles governing the uses of water vary in different sections of the United States, as do also the problems involved. In the arid States of the West, where the principal use of water is for irrigation, the doctrine of "prior appropriation" obtains, whereas in the humid States, where needs for domestic water supplies, sanitation, power development, and navigation are of primary concern, the doctrine of "riparian ownership" is recognized. In areas lying within the so-called semi-arid regions, no little conflict has arisen between these two doctrines, which it has been difficult to reconcile and adjust. In general, however, laws and Court decisions within the States in which these regions occur have made it possible, in a measure, for an appropriator, or user of water, to secure recognition of, and reasonable protection in, such uses.

In addition to the interstate decisions, the United States Supreme Court, in repeated decisions, down to the California Oregon Power Company case in 1935, has recognized the right of each State to adopt its own system of water law. The appropriation doctrine is an approved system of water law. In 1905 the Supreme Court stated[4] concerning alteration of the common law doctrine in Utah: "This court must recognize the difference of soil and climate, which renders necessary these different laws in the states so situated." In the California Oregon Power Company case, also, it was stated that the desert land legislation does not bind or purport to bind the States to any policy, but simply recognizes the doctrine of appropriation "and seeks to remove what otherwise might be an impediment to its full and successful operation."

The trend of recent decisions by the Supreme Court of the United States indicates a tendency to modify both of these fundamental doctrines so as to permit an "equitable apportionment," as between States, of the available water furnished by an interstate stream.

The uses and pollution of the waters of interstate streams, and the settlement of controversies between States, resulting from such uses or claims, constitute at present (1939) one of the most urgent problems with which the States and the Federal Government are confronted. A conflict of interests inevitably arises sooner or later on nearly every interstate stream. This fact becomes highly significant when it is realized that no general comprehensive plan, with respect to the development of an interstate stream, can be effective or satisfactory without co-operation between the States, and at times between the States and the Federal Government.

The riparian doctrine of the common law of England was adopted in the United States at an early date, and always has been the controlling principle of law governing the use of water in the humid regions and in parts of the semi-arid States. Under this doctrine, each riparian proprietor is entitled to have the stream come to his land as it would naturally flow, substantially undiminished in quantity, and unimpaired in quality. All riparian owners have an equal right to make reasonable use of the waters of a common stream consistent with their necessities. This right does not mean, however, that all users are entitled to equal quantities of water from the same source. This doctrine worked no particular hardship so long as the competitive demand for water was relatively low in relation to the available supply. As the demands for water increased, however, a rule so absolute and inflexible became increasingly impossible of strict application. Force of circumstances and necessity for continued existence compelled a modification, if not a theoretical abandonment, of the strict riparian doctrine.

---

[4] Clark *vs.* Nash, 198 U. S. 361.

Four decisions of the Supreme Court of the United States have laid down the principle of "Equitable apportionment" of the waters of an interstate stream, based on the "equality of right" existing between States. In the case of Kansas *vs.* Colorado[5] the controversy involved the use of the waters of the Arkansas River, which rises in the State of Colorado and flows into Kansas. The Government of the State of Kansas alleged that the depletion of the flow of the river by the irrigation of a large acreage in Colorado had injured its lands, institutions, and citizens. Recognizing, at the time only, the riparian doctrine, Kansas claimed the right to the entire flow of the river. Colorado, where the exclusive appropriation doctrine had been adopted in its Constitution, claimed the right to the use of all the waters arising within its boundaries, on the basis of its sovereign right of ownership in said waters. Notwithstanding the fact that Kansas as a State had suffered some damage from the depleted flow of the river, the Court decided: That, since Colorado lies entirely within the arid region, and due to the exigencies of its people as a result of such natural conditions, and the large development that had accrued in that State as a result of the theretofore large use of water by its citizens, "it would seem that equality of right, and equity between the two states, forbid any interference with the present use of water in Colorado"; but that further depletion of the water by Colorado might result in a situation in which "Kansas may justly say there is no longer an equitable division of benefits, and may rightfully call for relief." The decision in this case has been interpreted by many as establishing the principle of "equitable division" or "equitable apportionment" of the waters of an interstate stream.

In the case of Wyoming *vs.* Colorado,[6] involving the use of the waters of the Laramie River, which rises in Colorado and flows into Wyoming, the latter State alleged that a proposed diversion of water in Colorado from the Laramie River Basin, for the irrigation of lands outside that basin in the State of Colorado, by means of the so-called Laramie-Poudre Tunnel, would injure prior appropriators of water out of the Laramie River in Wyoming. Wyoming contended that priority of use, regardless of State lines, should prevail, and therefore that, since it had prior appropriations of a sufficient volume to consume the firm water supply of the river, it was entitled to protection for such appropriations. Colorado claimed the right to the use of all the waters originating within its boundaries, by reason of her sovereignty of Statehood. The Constitutions of both States recognize only the doctrine of prior appropriation and beneficial use.

---

[5] Kansas *vs.* Colorado, 185 U. S. 208; 206 U. S. 46 (1901–1907).

[6] Wyoming *vs.* Colorado, 259 U. S. 419–496; 260 U. S. 1 (1922).

Colorado claimed (*a*) wasteful use by Wyoming, (*b*) that Colorado uses would be more economical and more productive, (*c*) that the proposed tunnel diversion was an appropriation whose priority dated from 1902, and (*d*) that Colorado uses would not deplete the river at the State line beyond the demands of Wyoming priorities, which were earlier. There was an issue as to the seniority of appropriations in Wyoming, as compared with the tunnel appropriations, and it was not alone an issue of State sovereignty claim to the water.

The Court held that the doctrine of prior appropriation, recognized by both States, was applicable to a determination of the equities claimed by both States in the waters of the Laramie River and furnished "the only basis which is consonant with the principles of right and equitable application to such a controversy as this." Many attorneys have concluded that, in this decision, the Court decided the case strictly upon the principles of "priority of appropriation and use." Other authorities, however, are firmly of the opinion (*a*) that the principle underlying the decision was that of "equality of right" between the States and that of "equitable apportionment" of the benefits provided by the river; and (*b*) that a determination of the controversy, founded upon priority of appropriation and beneficial use in the two States under the doctrine announced in their respective Constitutions, would conform to the fundamental principle of equitable apportionment.

In this connection, the Court re-affirmed the principle laid down in the Kansas-Colorado[5] decision of equitable apportionment between the two States, adopting as a basis of equitable apportionment the doctrine of appropriation, recognized in both States, regardless of State lines.

In the case of Connecticut *vs.* Massachusetts[7] concerning a proposed diversion from the drainage area of the Connecticut River to provide water for the metropolitan area of Boston, Mass., Connecticut set up its right under the riparian doctrine, which both States recognized, to the undiminished flow of the river, and alleged that, to take water entirely out of the Connecticut River Basin, would impair the navigability of the Connecticut River, increase danger from pollution, and take away flood rights. In rendering its opinion, the Court clearly indicated abandonment of the riparian doctrine as applicable to interstate questions, and again enunciated the principle of "equitable apportionment" in the following language:

> "* * * but the laws in respect of riparian rights that happen to be effective for the time being in both states do not necessarily constitute a dependable guide or just basis for the decision of controversies, such as that herein presented. Such disputes are to be settled on the basis of equality of right, but this is not to say that there must be an equal division of the waters of an interstate stream among the states through which it flows. It means that the principles of right and equity shall be applied, having regard to the 'equal level or plane on which all the states stand, in point of power and right, under our constitutional system,' and that upon a consideration of the pertinent laws of the contending states, and all other relevant facts, this court will determine what is equitable apportionment of the use of such waters."

---

[7] Connecticut *vs.* Massachusetts, 282 U. S. 660 (decided February 24, 1931).

The case of New Jersey *vs.* New York,[8] concerning the Delaware River, involved a set of facts similar to those in the case of Connecticut *vs.* Massachusetts.[7] The Court again applied the doctrine of equitable apportionment by announcing "the effort is always to secure an equitable apportionment without quibbling over formulas," and decided that "removal of water to a different water shed obviously must be allowed at times unless states are to be deprived of the most beneficial use on formal grounds."

Under the appropriation doctrine, the individual or group that first makes a beneficial use of water thereby acquires a prior right to its continued beneficial use. As heretofore stated, practically all of the States of the arid and semi-arid West have adopted this doctrine. It was borrowed from foreign countries and first applied in New Mexico and Arizona, which, upon acquiring Statehood, adopted the exclusive doctrine of priority. In about 1849, this doctrine came into practice extensively in California, which has always recognized the riparian doctrine, or a modified form thereof. This early adoption of the appropriation doctrine in California resulted from the necessities of the situations obtaining in the old California mining days, when the rapid development of placer mining frequently created a demand for all available water furnished by a stream.

The community developed a system of "first come, first served," the claim dating from the time work was initiated. These activities all occurred on public lands. Congress later recognized such local laws and customs (and thereby the doctrine of appropriation) by an Act[9] of 1866, and confirmed this policy by subsequent legislation.[10] This doctrine appears to be firmly established, not only as a result of legislation to which reference has been made, and by such further legislation as that of the U. S. Reclamation Act and the Federal Power Act, but by decisions of the Supreme Courts in the various Western States and of the Supreme Court of the United States, notably that of Kansas *vs.* Colorado,[5] and Wyoming *vs.* Colorado.[6]

Federal Control over Water Resources.—The right of the Federal Government to exercise control over the waters of the nation is based primarily upon the constitutional power of Congress to regulate navigable waters. Congress has also exercised jurisdictional authority in connection with flood control, treaty obligations, and to a certain extent in interstate compacts and the use of the public domain.

This power is not granted expressly by the Constitution, but is incidental to, and based solely on, its power "to regulate commerce with foreign nations, and among the several States * * *" (Article I, Section 8, clause 3 of the Constitution). The power of Congress over navigable waters has been exercised from the outset and has been upheld by repeated decisions of the Supreme Court of the United States. The exercise of this power has not always been limited to control over streams and tributaries navigable in fact, but apparently has been extended to some streams in which navigability is really a fiction.

---

[8] New Jersey *vs.* New York *et al.*, 283 U. S. 336 (1931).

[9] Act of 1866, 14 Stat. 253.

[10] Act of July 9, 1870, 16 Stat. 217.

Federal control of water power is based primarily on the power of the Government to control navigable waters, but in certain instances also results from the use of public lands and reservations. The Acts of March 3, 1899, and June 23, 1910, forbid the construction of dams in navigable waters except upon affirmative authorization by Congress.[11] The numerous requests for special permission to construct dams for power purposes, and the work involved in determining whether or not the interests of the United States would be affected adversely by the proposed constructions, led to the creation of the Federal Power Commission[12] to relieve Congress of this burden, and to afford a more general determination of policy in such matters. The Act is the culmination of a steadily increasing assertion of Federal authority over navigable waters, by legislative construction of the constitutional power. Under this Act, control has been extended even to tributary streams which affect the navigable capacity of navigable streams. Perhaps a greater degree of authority is exercised over some phases of the development and use of power than strictly is required for navigation purposes. The lower Courts have upheld the Act, however, on the ground that its principal purpose is the protection of navigation.

Flood control projects of the Federal Government usually have involved the protection or promotion of navigation, which affords unquestionable constitutional authority for this type of work. The Federal Government, doubtless, also has power to build flood-control projects to protect interstate commerce over highways and railroads, the postal service, and the lives and safety of its citizens. The Act of March 1, 1917, authorized examinations, surveys, and reports on flood-control projects generally, and flood-control development work on the Mississippi and Sacramento Rivers.[13] Under the Act of January 21, 1927, the War Department has prepared about 185 Reports (known as the 308 Reports), covering investigations and surveys of many of the principal streams of the country with respect to navigation, flood control, water power, irrigation, and related features.[14] Prior to 1936, however, Congress based its approval of flood-control projects upon the theory that they were in the interest of navigation.

The Federal Government, through its authority in the matter of rights of way over the public domain, has been able to exercise considerable control over the use of water in the public-land States, especially where its interests, due to reclamation or forestation, were involved. The reclamation of Federal lands was really the basis of the Reclamation Act of 1902 under which the Bureau of Reclamation operates.[15] As a result of its construction activities, this Bureau has exercised, indirectly, a certain degree of control over the development and administration of the waters of interstate streams on which some of its projects are located.

The question of State *vs.* Federal ownership of the unappropriated waters of the public-land States has long been debated by proponents of both theories, who, in support of their views, have cited numerous decisions of the Supreme Court touching upon this important matter.

[13] Act of March 1, 1917, 39 Stat. 950.

[14] Act of January 21, 1927, 44 Stat. 1010; H. R. Doc. 308, 69th Cong., 1st Session (see also, Flood Control Acts of 1936 and 1938).

[15] Reclamation Act of 1902, 32 Stat. 388.

One theory, known as the "California Doctrine," holds that, when the Federal Government originally acquired the territory which now constitutes the State of California, it became not only the owner of the lands, but also the owner, in a strict and proprietary sense, of the right to the use of the waters appurtenant to these lands; and further that the conference of Statehood passed political powers and not proprietary rights. The leading case in support of this theory is that of Lux *vs.* Haggen.[16]

Under the opposing theory, generally known as the "Colorado Doctrine," the Federal proprietary title to water is denied, and all rights to water within the confines of the State are held to be vested in the State for the use of the public. Under the theory of State sovereignty and State law, this doctrine is written into the Constitution of the State of Colorado, as well as in those of several other States of the arid West. The proponents of this doctrine contend that the Congress of the United States recognized and accepted such doctrine in the Enabling Acts under which the States came into the Union.

Although, on numerous occasions (notably in Kansas *vs.* Colorado[5]), the Federal Government has asserted its claim to the ownership of all of the unappropriated waters of the public-land States of the West, the question as to whether the Supreme Court of the United States has definitely spoken in regard to this important matter is probably not open to debate. The United States Supreme Court permitted the Government to file a petition in intervention of Nebraska *vs.* Wyoming, in which Colorado was an impleaded defendant; such action would not constitute a final adjudication of the rights of the Federal Government to remain in the suit.

On Wyoming's motion to dismiss in this case,[17] the U. S. Supreme Court, in 1935, expressly declared that the water belongs to the State:

> "The motion asserts that the Secretary of the Interior is an indispensable party. The bill alleges, and we know as matter of law, that the Secretary and his agents, acting by authority of the Reclamation Act and supplementary legislation, must obtain permits and priorities for the use of water from the State of Wyoming in the same manner as a private appropriator or an irrigation district formed under the state law. His rights can rise no higher than those of Wyoming, and an adjudication of the defendant's rights will necessarily bind him."

In discussing the effect of the Reclamation Act, the Court, in 1935, came to the same decision in California-Oregon Power Company *vs.* Beaver Portland Cement Company[18]—namely, that the Government, as owner of the public domain, had the power to dispose of the water separately and did dispose of it separately to the States. In 1937, this was followed by the U. S. Supreme Court in Ickes *vs.* Fox[19] where it is declared:

> "The Federal Government, as owner of the public domain, had the power to dispose of the land and water composing it together or separately;

[17] Nebraska *vs.* Wyoming, 295 U. S. 40; 79 L. ed. 1289 at p. 1291.

[18] California-Oregon Power Company *vs.* Beaver Portland Cement Company; 295 U. S. 142, 79 L. ed. 1356.

[19] Ickes *vs.* Fox, 300 U. S. 82, 81 L. ed. 525, 530.

and by the Desert Land Act of (March 3) 1877,[20] if not before, Congress had severed the land and waters constituting the public domain and established the rule that for the future the lands should be patented separately. Acquisition of the government title to a parcel of land was not to carry with it a water-right; but all non-navigable waters were reserved for the use of the public under the laws of the various arid-land states."

The Court there held that the United States was not an indispensable party defendant, even if it had built a reclamation project which used water from the stream; and, that the ownership of the water right is in the land-owners and not in the United States.

The final decision of the Court in the suit over the waters of the North Platte River should definitely dispose of this long-disputed question.

The Federal Government unquestionably has control over the waters of an international stream, in so far as such authority may be needful in the negotiation and ratification of an international treaty concerning use of such waters. It is also probable that the Federal Government has similar authority in carrying out any specific obligation that it incurred in connection with its Indian charges with respect to public waters prior to Statehood.

State Control over Water Resources.—As heretofore stated, it is the theory and contention of the States in the arid region that control of the waters within their boundaries lies exclusively with such States, and most of them have declared, by constitutional provision, or by legislative enactment, that such waters are the property of the State or of the public. Most of these States have legislative codes providing a complete system by which rights to the public waters of the State may be recognized and determined by adjudication proceedings. The latter are usually by Court action, and for the administration of the rights of the appropriators, if such rights have been determined, as required by statute. Such system provides quite complete control over the appropriation, administration, and use of the public water supplies of these States. In some public-land States, where the doctrine of appropriation does not apply, and especially in the States east of the Mississippi River, there has never been any question as to the power of a State to control the waters within its boundaries, there being no Federal interests, except in connection with navigation, or diversions from one drainage basin to another. The extent of State control varies from practically no control in some of the Southern States to complete control over all water uses and developments, as in the States of New York, Maryland, and Pennsylvania.

Present Methods of Settling Interstate Water Problems.—Interstate water controversies may be settled by: (*a*) Original suits between States in the Supreme Court of the United States; (*b*) review of decisions in the lower Federal Courts between individual or corporate interests; and (*c*) interstate compacts or treaties. The Supreme Court is the only agency having jurisdiction over interstate water controversies between States with authority to effect a division of the waters of an interstate stream. In Missouri *vs.* Illinois, in connection with its authority, the Court has announced[7, 21] that "the governing rule is that this Court will not exert its extraordinary power to control the conduct of one state at the suit of another, unless the threatened invasion of rights is of serious magnitude and established by clear and convincing evidence."

---

[20] Desert Land Act of March 3, 1877, Chapter 107, 19 Stat. at L. 377, 43 U. S. C. A., Section 321.

[21] Missouri *vs.* Illinois, 200 U. S. 496 (1906).

Suits between private parties in different States concerning the waters of interstate streams merely settle individual controversies and afford little, if anything, in the solution of the larger interstate problems. Where the findings of the lower Federal Courts, however, are reviewed by the Supreme Court, the results of such suits have all the force and effect upon the litigants, and possibly also upon such States in which the waters flow, as if the findings were the result of an original suit between such States.[22]

Voluntary, informal interstate agreements have been resorted to in an attempt to adjust or settle interstate problems, aside from recourse to the Courts. A notable example is the Ohio River Interstate Stream Conservation Agreement, entered into in 1924 between the Health Departments of Ohio, West Virginia, Pennsylvania, and subsequently by eight other interested States, for the purpose of conserving the waters of interstate streams and preventing undue pollution. The co-operative activities of the States under this agreement still continue, but a formal compact has been drafted. Such agreements afford some opportunity for the development and administration of the waters of those streams, but because of their *quasi* legal character, have no power of apportionment of the waters thereof between the States.

Fusion of public, State, and administrative agencies, by concurrent legislation of the States, has also been employed as a means of settling interstate problems. The New York-New Jersey Port Authority was thus created for purposes of planning and financing important undertakings, but has no authority to enforce its activities against either State.

BASIC PRINCIPLES ENUNCIATED BY THE SUPREME COURT OF THE UNITED STATES WITH RESPECT TO INTERSTATE WATER CONTROVERSIES

In the fifteen decisions heretofore rendered by the Supreme Court of the United States, involving the waters of interstate streams, the Court has announced and applied a number of fundamental or underlying principles applicable to such controversies. These fundamental principles are reviewed in the case of Connecticut *vs.* Massachusetts,[7] decided February 24, 1931, and are as follows:

(*a*) That of "equality of right" between States;[5, 7]

(*b*) That each State has full jurisdiction over the lands within its borders, including the beds of streams and other waters;[5]

(*c*) That a State may determine for itself whether the riparian or appropriation doctrine shall control as regards the waters within its boundaries, and is free to change its system;[4, 7, 23, 24]

(*d*) That "whenever the action of one state reaches through the agency of natural laws into the territory of another state, the question of the extent and limitations of the rights of the two states becomes a matter of justiceable dispute between them";[5, 8]

---

[22] Pioneer Irrigation Co. *vs.* John E. Field and A. A. Weiland as State Engineers of the State of Colorado, 259 U. S. 498.

[23] United States *vs.* Rio Grande Irrigation Co., 174 U. S. 690–702.

[24] California-Oregon Power Co. *vs.* Beaver Portland Cement Co., *et al.*, 73 Fed. 2d 555.

(*e*) That no State may claim the exclusive right to the use of all the waters within its boundaries; that there must be an equitable division or apportionment of the benefits of an interstate stream between the States affected;[5, 6, 7, 8, 21, 25]

(*f*) That, as between two or more States which recognize exclusively the doctrine of appropriation and beneficial use, such doctrine may properly be made the basis in a determination of equitable apportionment of the common water supply[26] (priority of appropriation, however, does not necessarily create superiority of right in the waters of an interstate stream;[8] see also Item (*e*));

(*g*) That water may be taken from one drainage basin for use in another drainage basin, although such diversions may result in some injury to the basin in which such waters originate;[6, 8]

(*h*) That the burden of constructing storage reservoirs for conserving the surplus waters of an interstate stream, which otherwise would run to waste, rests upon the lower State, and an upper State is not required to give up waters, which it may need, to a lower State, when such practice would result in waste of the common supply;[6]

(*i*) That the appropriators and users of water in a State are represented by the State under which their claims arise, and are bound by the limitations which may be imposed upon that State, either by Supreme Court decree or by interstate compact;[17, 27, 28]

(*j*) That the United States may perform its functions without conforming to the police regulations of a State; that, where such authority is involved (such, for instance, as the constitutional right to control navigable waters), it is immaterial if other benefits such as flood control, reclamation, conservation, apportionment of the waters between States, or the performance of an international obligation may result from the exercise of such constitutional power;[29, 30]

(*k*) That the "Court cannot issue declaratory decrees"[8, 30] (since the decisions affecting Item (*k*) were rendered,[8, 30] Congress has empowered Federal Courts to render declaratory decrees. However, this authority may or may not be considered as applying only to Federal District Courts);

(*l*) That "to appropriate water means to take and divert a specified quantity thereof and put it to beneficial use in accordance with the laws of the State where such water is found and, by so doing, to acquire under such laws a vested right to take and divert from the same source, and to use and consume the same quantity of water annually forever, subject only to the right of prior appropriators";[30]

---

[25] Georgia *vs.* Tennessee Copper Co., 206 U. S. 230–237.

[26] Wyoming *vs.* Colorado, 259 U. S. 419; 260 U. S. 1; 286 U. S. 494; 298 U. S. 573.

[27] Wyoming *vs.* Colorado, 286 U. S. 494 (1932).

[28] Hinderlider *et al. vs.* La Plata River and Cherry Creek Ditch Company, 58 S. Ct. Rept. 803 (decided April 25, 1938).

[29] Wisconsin *vs.* Illinois *et al.*, 278 U. S. 395 (1929).

[30] Arizona *vs.* California *et al.*, 283 U. S. 423 (1931).

(*m*) That an upper State is not relieved of its responsibility for damages inflicted upon a lower State as the result of an increase of flow in an interstate stream by the drainage of lands in the upper State:

> "Right of a state as parens patriae to bring suit to protect the general comfort, health and prosperity of its inhabitants, threatened by the proposed or continued action of another state by prayer or injunction is to be differentiated from its lost power as a sovereign to prevent and impose individual claims of its citizens as their trustees against a sister state."

The Eleventh Amendment to the Constitution of the United States provides:

> "The judicial power of the United States shall not be construed to extend to any suit in law or equity, commenced or prosecuted against one of the United States, by citizens of another state, or by citizens or subjects of any foreign state."

Neither may a citizen of a State prosecute a suit in law or equity against another State;[31]

(*n*) That "the governing rule is that this court will not assert its extraordinary power to control the conduct of one state in the suit of another, unless the threatened invasion of rights is of such serious magnitude and established by clear and convincing evidence";[21, 32]

(*o*) "Injunction issues, to prevent existing or presently threatened injuries, will not be granted against something merely feared as liable to occur at some indefinite time in the future."[7, 8, 30, 32] That "the burden on the complaining state of sustaining its allegations is much greater than that generally imposed upon a complainant in an ordinary suit between private parties";[31]

(*p*) The laws in respect to riparian rights that happen to be effective for the time being in both States do not necessarily constitute a dependable guide or just basis for the decision of controversies such as that presented here. The rules of the common law on that subject do not obtain in all of the States of the Union, and there are variations in their application. The doctrine of appropriation prevails in some States, and every State is free to change its laws covering riparian ownership and to permit the appropriation of flowing waters for such purposes as it may deem wise;[7, 23]

(*q*) That, in a given case, a division of the waters of an interstate stream may not necessarily create a prior appropriation or superiority of right over another State in the enjoyment and use of the waters of an interstate stream;[8]

(*r*) That, where the Court has by decision equitably divided the waters of an interstate stream between two States, the apportionment or quantum received by each State may be administered for the benefit of its appropriators, in accordance with its own laws, without regard to the interests of the other State, so long as the aggregate quantity so allocated is not exceeded;[27]

(*s*) That the appropriators or water users under a Federal reclamation project obtain whatever rights they may have to the use of water from the States in which such projects are located, and the continued enjoyment of such right is subject to the laws of such State;[5, 33]

(*t*) That States have the unquestioned authority to agree upon the division and use of the waters of an interstate stream, even if such division and use may have the effect of disturbing or destroying the rights of individual appropriators which had theretofore been recognized by the laws of either State;[28]

(*u*) That the highest use of interstate waters is for drinking and other domestic purposes;[7]

(*v*) That States may select sources of water supply, provided no substantial damage is done to sister riparian States;[8]

(*w*) That release of compensatory water depends upon down-stream river conditions and needs;[8]

(*x*) That judicial allowance of diversions affecting navigation or navigable capacity is conditioned upon Federal approval.[7, 8, 34]

Original Cases Between States Before the Supreme Court of the United States

Arkansas River Suit.—Litigation between Colorado and Kansas over the waters of the Arkansas River has been practically continuous for the thirty-six years, 1904–1939. In the noted suit brought by Kansas against Colorado in 1901,[35] the U. S. Supreme Court decided that, although certain irrigation interests in western Kansas had been injured by diversions of water from the Arkansas River in Colorado, such diversions by Colorado had not exceeded its equitable share of the waters of this interstate stream, and dismissed the case without prejudice to Kansas to reinstate a suit at a later date, if continued diversions in her judgment justified such action. Up until 1929, Kansas failed to institute action for any relief to which that State might have felt it was entitled since the former decision. Almost immediately after the decision of the former suit in 1907, administrators of certain ditches in Kansas instituted suit in 1910 in the Federal Court for the District of Colorado against a large number of agencies that controlled ditches and reservoirs in Colorado, impleaded in the former suit, seeking to restrain the latter from diverting water in Colorado to their alleged injury. This case is known[36] as the United States Irrigating Company *vs.* Graham Ditch Company suit. This case was settled out of Court in 1916, but a later suit was instituted in the same Court in 1917 by one of the Kansas ditch companies not a party to the settlement against the same ditch companies in Colorado mentioned in the former suit[37] and later amended to include ditches and reservoirs on the tributaries of the Arkansas in Colorado (Coler Ditch and Reservoir). This condition resulted in Colorado, in her sovereign capacity, filing suit in the Supreme Court of the United States in 1929 against the State of Kansas for the purpose of requiring the latter State to enforce upon its water users the provisions of the former Supreme Court decree, and to quiet further litigation by her agents against appropriators in Colorado. The Supreme Court of the United States assumed jurisdiction of the subject matter and permitted Colorado to file an original suit against

[37] Finney Co. Water Users Association *vs.* Graham Ditch Co. *et al.*, 1934 Colorado, 1 Fed. 2d, 650.

the State of Kansas. In its answer, Kansas filed a cross bill of complaint against Colorado in which, among other things, Kansas alleged increased depletion of the flow of the river, since the original case had been decided, and also its right to one-half of the undepleted flow of the river at the Colorado-Kansas State line. Voluminous testimony, covering a period of nearly ten years, has been taken in this second suit before a stenographic commissioner, appointed by the Court.

In the meantime, the representatives of the two States entered into a stipulation to maintain the *status quo* of the use of the waters of the Arkansas River pending: (*a*) The construction of a large storage and flood-control reservoir, which is known as the Caddoa Reservoir, to be located on the Arkansas River about 40 miles west of the Colorado-Kansas State line and which has been approved for construction by the United States Corps of Engineers in the Omnibus Flood Control Act of 1936; or (*b*), until the present suit has been decided by the Court.

The *status quo* provided by the stipulation is described as permitting Colorado to continue to divert substantially 160 000 acre-ft of water per yr for the irrigation of 72 000 acres of land below the Caddoa Reservoir in Colorado, and that Colorado will not deplete the flow at the interstate line below 25 000 acre-ft, in order to permit storage in reservoirs in western Kansas between October 1 and April 1, and not below 52 000 acre-ft for direct application in Kansas between April 1 and October 1; that when the Caddoa Reservoir has been constructed, both States will share equally in the surplus water which the reservoir will capture and make available under the administration of the two State Engineers. The stipulation is without prejudice to the claims of either party, as set out in the pending interstate suit, and is subject to the decision of the Supreme Court of the United States as to the respective rights of the States to the water furnished by the Arkansas River, or stored in the proposed reservoir. The stipulation provides that its terms shall not be filed in the present action between the States until the construction of said dam and reservoir by the United States Government has been assured. The two States agreed to co-operate in obtaining the construction of the Caddoa Dam. In this connection, the Legislature of Colorado created the Caddoa Reservoir and Arkansas River Basin Conservancy and Improvement District to enable the water uses to meet any obligations imposed by the Federal Government in connection with the construction of the Caddoa Dam.

Laramie River Suit.—This case[6] involved the use of the waters of the Laramie River which rise in Colorado and flow into Wyoming. The Government of the State of Wyoming alleged that a proposed diversion, by means of a tunnel from the Laramie River to the Cache la Poudre River in Colorado, would injure prior appropriators in Wyoming. In their Constitutions both Wyoming and Colorado recognize only the doctrine of appropriation, but Colorado claimed the right to the use of all of the waters within her borders by reason of sovereignty or statehood. Wyoming contended that priority, regardless of State lines, should apply, and that Wyoming, having prior appropriations of sufficient volume to use practically all of the waters of the river, was entitled to full protection in such uses.

The U. S. Supreme Court, however, did not accept the priority date (1902) given the tunnel by the Colorado State Court, but set it back 7 yr to 1909, which put it behind many large intervening priorities in Wyoming and thereby reduced the remaining flow available for the Laramie-Poudre Tunnel. It imposed an acre-foot per acre of use limit on Colorado meadows and rejected the Colorado greater-productivity consideration.

The Court held as follows:

(*a*) That the doctrine of prior appropriation, recognized by both States, was applicable to interstate streams and controversies, and furnished "the only basis which is consonant with the principles of right and equity applicable to such a controversy as this";

(*b*) That Colorado's claim to all the waters within its boundaries was untenable;

(*c*) That water-shed trans-basin diversions are permissible where both States recognize such diversions within their respective boundaries;

(*d*) That the burden of conserving, by storage reservoirs, the surplus waters of a stream is upon a lower State, which has the effect of relieving the upper State of the obligation to pass water to a lower State when such action may result in waste; and

(*e*) That there was no need to pass on the contention of the United States that all unappropriated waters of the Western States belong to the United States and, therefore, are already removed from State control.

One of the interesting results of this suit was the fact that, in allocating the entire water supply furnished by the Big Laramie River in Colorado and Wyoming, the Court arrived at its decision by first determining the total water supply furnished by the stream. It recognized the then existing uses in both States, based upon their relative orders of priority, as determined by State laws. This sum total was deducted from the total water supply, which left a residue of 15 500 acre-ft of water per yr, which the Court allocated to the Laramie-Poudre Tunnel, a Colorado appropriator. As determined by the Court, this tunnel was the most junior appropriator on the stream in both States, but the decision of the Court made its appropriation, to the extent of 15 500 acre-ft annually, actually senior to any appropriation out of the river in Wyoming. As a result of later years of subnormal stream flow, many senior appropriations in Wyoming have lacked water, whereas the tunnel each year diverts all that it is physically possible to divert up to 15 500 acre-ft.

The second suit over the waters of this river[38] was filed by Wyoming against Colorado on October 6, 1930. This suit involved the interpretation of the decree of the U. S. Supreme Court entered in the former suit. The decision of the Court, announced June 1, 1936, sustained the contentions of Colorado that the quantities of water, theretofore recognized by the Supreme Court in the former case as having been diverted out of the Laramie River by agencies in Colorado, were in the nature of an allocation of waters to the State of Colorado, and not to its individual water users, and that Colorado could rightfully administer such *quantum* under the provisions of its own laws without violating the interests of Wyoming, so long as such *quantum* (which was fixed at 39 750 acre-ft in any one year) was not exceeded.

---

[38] Wyoming *vs.* Colorado, 298 U. S. 573.

The decision, however, had the effect of discontinuing two small trans-mountain diversions, which were not mentioned in the former proceeding, out of the Laramie River to the Cache la Poudre River. Colorado's interpretation of the words "divert and take" in the former decree, with reference to the meadowlands, meant a consumptive use and not head-gate diversions. The Court held, however, that previous head-gate diversions of these meadowland ditches resulted in an unnecessary use of water and that the actual consumptive use of water on wild meadowlands in Colorado, which was found equal to 1 acre-ft per acre actually irrigated, should be measured at the head-gate of the ditches.

Because of the practice of flooding peculiar to this type of crop, enforcement of the decree will have the effect of destroying the greater part of about 4 250 acres of hay lands in Colorado. The Court gave the State of Colorado until September 15, 1938, to file application for a rehearing in respect to that part of the decision relating to the meadowlands. The Court denied Wyoming's demand that an interstate bailiff be designated by the Court to administer the waters of this stream, and left the administration of the stream in the hands of the State Engineers of the two States; but it retained jurisdiction of this phase of the case for the purpose of affording Wyoming relief in the event that future difficulties of administration between the States justified such relief.

Chicago Lakes Drainage Cases.—This suit[39] was instituted by the State of Wisconsin and other States against the State of Illinois and the Sanitary District of Chicago, Ill., to enjoin defendants from withdrawing 8 500 cu ft of water per sec from Lake Michigan. The Sanitary District of Chicago increased diversions from Lake Michigan through the Chicago drainage canal from 4 167 to 8 500 cu ft per sec in violation of a permit theretofore issued by the War Department. Later, the War Department authorized this increase for purposes of sewage dilution. The Court held that, in so far as the diversion was not for the purpose of navigation in the Chicago River, it was without legal basis and could be enjoined by the States bordering on the Great Lakes and having riparian rights that were being injured by the lowering of the level of the lakes.

The matter was referred by the Court to a Master to take testimony and make findings of facts. Following the report of the Master, the Court entered a decree in accordance with his opinion and recommendation and required the Sanitary District of Chicago to provide proper treatment facilities to reduce the diversions through the drainage canal.[40]

In its reply, the Chicago Sanitary District pleaded its inability to finance the obligations imposed by the Court. Upon recommendation of the Master, permission was given to divert an enlarged quantity of water and for extension of time for the State of Illinois to finance the cost of necessary sewage disposal works, which the Court required that State to meet.

[40] Wisconsin *vs.* Illinois, *et al.*, 50 S. Ct. 256 (1930).

Connecticut River Suit.—This original suit[7] was brought by Connecticut to enjoin Massachusetts and the Boston, Mass., Metropolitan Water District from diverting water from the Swift and Ware rivers, tributaries of the Connecticut River in Massachusetts, for use in the Boston Metropolitan area, which had been authorized by the Legislature of Massachusetts and permitted by the Secretary of War, under certain limitations and requirements. Connecticut established its right, under the doctrine of riparian ownership which both States recognize, to the undiminished flow of the river, and alleged, among other things, that the riparian doctrine forbade such diversions out of the water-shed, and that to take water entirely out of the Connecticut River Basin would impair the navigability of the Connecticut River, the fishing industry, agriculture, power development, increase dangers from pollution, and take away flood rights.

The Special Master, appointed by the Court to take the testimony, upheld the right of the City of Boston to construct the proposed project, and held that the damage that would result to navigation, agriculture, and to the sanitary condition of the Connecticut River by the proposed project would be inconsequential.

In rendering its opinion, the Court apparently abandoned the exclusive riparian doctrine as applicable to interstate questions, and announced another principle by the statement:

> "* * * but the laws in respect to riparian rights that happen to be effective for the time being in both states do not necessarily constitute a dependable guide or just basis for the decision of controversies such as that here presented. Such disputes are to be settled on the basis of equality of right, but this is not to say that there must be an equal division of the waters of an interstate stream among the states through which it flows. It means that the principles of right and equity shall be applied, having regard to the 'equal level or plane on which all the states stand in point of power and right under our constitutional system,' and that upon consideration of the pertinent laws of the contending states, and all other relevant facts, this Court will determine what is an equitable apportionment of the use of such waters."

The Court also established the principle that an injunction will not be granted against something merely feared as likely to occur at some indefinite time in the future.

The Court also held that a diversion of a State's equitable share of the water to another water-shed was not in itself ground for injunctive relief, and that a State had the right to select its own source of water supply, provided that such action would not result in serious damage to other States. In its ruling, the Court recognized the limitation of diversions by the Boston Metropolitan area, of the waters of the Swift and Ware rivers, imposed by the Secretary of War in the interest of navigation.

Delaware River Suit.—This action[8] was brought by the State of New Jersey to prevent the State of New York from diverting waters from certain tributaries of the Delaware River, an interstate stream common to the States of New Jersey, New York, Pennsylvania, and Delaware, and from the water-shed of the Hudson River, for the purpose of increasing the water supply of the City of New York.

In 1923, the Legislatures of New Jersey, New York, and Pennsylvania authorized appointment of Commissioners who negotiated a Compact allocating the water resources of the Delaware River between the three States. The Compact was ratified by the Legislature of New York only. A second Compact, negotiated in 1927, provided for the diversion of 600 million gal of water daily from the Delaware River and its tributaries by New York, 600 million gal daily by New Jersey, and 900 million gal daily by Pennsylvania, with provisions for released flows. This second Compact was not ratified by New Jersey or Pennsylvania.

New York then proceeded with its plan for diverting 600 million gal per day from tributaries of the Delaware River, and for releasing water in accordance with the terms of the last Compact, which plan was approved by the Water and Power Control Commission of New York State. New Jersey filed its bill in the U. S. Supreme Court to enjoin the State and City of New York from continuing with this plan, alleging among other things that it would cause substantial damage to navigation, power development, sanitary conditions, industrial use, fisheries, and other uses, and that it would violate riparian rights, particularly by diversions out of the water-shed.

The Court permitted Pennsylvania to intervene in behalf of its own interests in the river. The decision of the Court was handed down on May 4, 1931. The decision permitted New York to divert 440 million gal per day, a quantity less than claimed by that State, subject to certain reservations.

It is interesting to note that, in recognizing the right of New York to make such diversions, it enunciated the important principle that, in the absence of a compact between the States, such diversion by New York does not constitute a prior appropriation, and shall not give the State of New York, and the City of New York, any superior right over New Jersey and Pennsylvania in the enjoyment and use of the Delaware River and its tributaries.

In this case, as in the case of Arizona *vs.* California *et al.*,[30] the Court held that it was without power to render a declaratory judgment to prevent the consummation of that which is merely feared as likely to occur. The Court dismissed the bill of complaint of New Jersey without prejudice to the equities of New Jersey and Pennsylvania in the waters of that stream basin.

The Court held that,

> "* * * although one state has the physical power to cut off all water within its jurisdiction from flowing into a river constituting a boundary between states, the exercise of such power to the destruction of the interests of the lower state, could not be tolerated, and likewise that neither will a lower state be permitted to require an upper state to give up its power altogether in order that the river may flow to the lower state undiminished; that both states have relative and substantial interests in an interstate river, which must be reconciled as best they may be."

This case involved a set of facts similar to those in Connecticut *vs.* Massachusetts.[7] In this case, the Court again applied the doctrine of equitable apportionment, and stated that "* * * the effort is always to secure an equitable apportionment without quibbling over formulas"; also that "* * * the removal of water to a different watershed obviously must be allowed at times unless states are to be deprived of the most beneficial use on formal grounds."

Colorado River Suit.—In this case,[30] Arizona filed its bill of complaint against the Secretary of the Interior, the State of California, and the other States of the Colorado River Basin, alleging, among other complaints, that the construction of a dam in the Colorado River at Black Canyon would invade the sovereign rights of the State of Arizona by diverting a part of the waters of the Colorado River for consumptive use elsewhere, and thus would interfere with the beneficial consumptive use by the State of Arizona of the unappropriated waters of the river flowing in that State. The Court held: (*a*) That the authority of the Secretary to construct the dam (later named the "Hoover Dam") was a valid exercise of the power of Congress, since the purposes enumerated included that of improving navigation; (*b*) that there was then no present threat of any act by the defendants which would interfere with the enjoyment by Arizona of any present or future appropriation of water out of the Colorado River by that State; and (*c*) that Arizona had not constructed any diversion works to divert the waters claimed. In this connection it is of interest to note that the Court clearly defined the status of an "appropriator of water" as follows:

> "* * * to appropriate water means to take and divert a specified quantity thereof and put it to beneficial use in accordance with the laws of the state where such water is found, and by so doing, to acquire under such laws a vested right to take and divert from the same source, and to use and consume the same quantity of water annually forever, subject only to the right of prior appropriators."

The bill was dismissed without prejudice to Arizona to make application for relief in case the water stored in Lake Mead was used in any way such as to interfere with the enjoyment by Arizona of any right already perfected, or with the right of Arizona to make additional legal appropriations. All the citations affecting this case[41, 42, 43] involve the Colorado River Compact and Boulder Canyon Project Act.

Walla Walla River Suit.—The purpose of the suit,[32] as disclosed by the allegations of the complaint and the relief sought, was to have the Court determine the relative rights of the State of Washington and Oregon to the use of the waters of the Walla Walla River and its tributaries, flowing within both States, and to enjoin the State of Oregon from continued interference with the rights of the State of Washington. The State of Washington alleged: (*a*) That the continued diversions of water from the tributaries of the Walla Walla River in Oregon would work irreparable injury to the State of Washington and its land owners unless restrained; (*b*) that both States, by their statutes and decisions of their Courts, recognize the doctrine of riparian ownership, and that the owner of land riparian to a stream is entitled to his proportionate share of the waters of such stream for the purpose of irrigation, subject to the requirement that such riparian user shall beneficially apply such water within

---

[43] United States *vs.* California, 295 U. S. 174 (1935).

a reasonable time; and (*c*) that each of said States further recognizes the doctrine of appropriation whereby the first appropriator in time is first in right, subject only to vested riparian rights.

In the same term in which it rendered the decision in the second Wyoming *vs.* Colorado suit,[6] the Court illuminated the principles which would actuate it in equitable apportionment. In Washington *vs.* Oregon,[32] decided March 2, 1936, both States stipulated for the purposes of that case that the individual rights of the respective landowners and water owners concerned in both States are governed by the doctrine of prior appropriation, so that question was not in issue.

In deciding against Washington, the Court related as impelling considerations that, due to the porous and gravelly formation in the river-bed, only a small portion of water would go by even if the dams of Oregon users were removed. "Fifty years of long established possession and uninterrupted use by the Oregon appropriators" were repeatedly commented on and given weight by the Court, since, said Justice Cardozo, to restrain the diversion

> "* * * would bring distress and even ruin to a long-established settlement of tillers of the soil for no other or better purpose than to vindicate a barren right. This is not the high equity that moves the conscience of the court in giving judgment between states * * *. In default of reasons for removal more urgent and compelling, the tillers of the soil will be left where they have settled.
>
> "In such circumstances, an injunction would not issue if the contest were between private parties at odds about a boundary. Still less will it issue here in a contest between states, a contest to be dealt with in the large and ample way that alone becomes the dignity of the litigants concerned."

A priority decree as of 1892 by Washington Court for the Gardena Ditch claim was held "of no force against Oregon or Oregon appropriators not parties to the suit," and the appropriation lost by laches and abandonment while Oregon rights were being matured.

The Court held that the State of Washington was not entitled to injunctive relief against Oregon under the evidence showing diversions by Oregon water users for domestic and agricultural purposes for 50 yr, and upon demonstration that, at periods of shortage of stream flow, only a small quantity of water would escape, even if not diverted, and would be lost in deep gravel formations beneath the stream channels.

The Court held that the priority dates and quantities awarded an appropriator by the Courts of his own State were not necessarily binding on the appropriators from the same stream in another State.

Rio Grande Suit.—Charging that rights to water from the Rio Grande for irrigation, dating back to 1861, were being violated by the State of New Mexico, and the Middle Rio Grande Conservancy District and its officials, the State of Texas commenced an original action[44] before the United States Supreme Court at the October term of that Court in 1935 to enjoin them from making any increased storage or diversions beyond those in existence prior to January 23, 1906.

---

[44] Texas *vs.* New Mexico and the Middle Rio Grande Conservancy District; disposed of by Rio Grande Compact now (1939) in force.

The complaint detailed the circumstances which caused the Republic of Mexico, in the early 1890's, to make complaints to the Federal Government that diversions of water on the upper stream had deprived Mexican lands of similar irrigation water supplies. This was followed by the establishment of an International Boundary Commission and a treaty which assured to Mexico a certain flow perpetually. Thereafter, the Elephant Butte Dam was constructed near Engle, N. Mex., at a cost of about $14 000 000.

Texas charged that New Mexico had violated that clause of the Rio Grande Compact which had been entered into by those two States with Colorado and which had been approved by Act of Congress dated June 17, 1930, and extended by a similar Act on June 5, 1935. The section in question provided:

> "New Mexico agrees with Texas, with the understanding that prior vested rights above and below Elephant Butte Reservoir shall never be impaired hereby, that she will not cause or suffer the water supply of the Elephant Butte Reservoir to be impaired by new or increased diversion or storage within the limits of New Mexico unless and until such depletion is offset by increase of drainage return."

New Mexico, and particularly the Middle Rio Grande Conservancy District, was accused of having constructed various permanent diversion dams, including the El Vado Reservoir with a capacity of 200 000 acre-ft, and with making greatly increased diversions of water upon increased acreages since the execution of the Compact.

The complainant's right to this water was based upon two filings made by the Reclamation Service in the office of the State Engineer of New Mexico on January 23, 1906, for 730 000 acre-ft near Engle, and on April 8, 1908, for all of the unappropriated water of the Rio Grande for storage in the Elephant Butte Reservoir. It was likewise charged that New Mexico had not offset such increased storage and diversions by drainage, and that the supply of the Elephant Butte Reservoir had been greatly impaired, both in quantity and quality.

New Mexico joined issue on the allegations of the bill, and the matter was referred to a Special Master by the U. S. Supreme Court. Evidence was taken at a series of hearings held in the two States over a long period of time, during which Texas presented extended testimony as to the impairment of the quality of water because of the presence of great quantities of salts deleterious to plant life.

In the Summer of 1937, the hearings were temporarily suspended until the Fall of 1938. In the meantime, the representatives of the three States, acting upon the facts disclosed by the joint investigation of the Rio Grande Basin by the National Resources Committee, signed the Rio Grande Compact on March 18, 1938. The compact has been ratified by the Legislatures of the three States and has been approved by the Congress, which actions settle all questions of dispute between the States and their agencies and disposes of this Interstate suit.

By the terms of this agreement the waters of the Rio Grande are equitably apportioned between the three States, with the rights of the Republic of Mexico fully protected and considered, and "all controversies between said three states relative to the quantity or quality of the water of the Rio Grande are composed and settled." The ratification of the Compact will undoubtedly result in the dismissal of the pending litigation, and another victory will have been "chalked up" for the exponents of the Compact method of composing differences between States.

North Platte River Suit.—On October 15, 1934, the State of Nebraska filed its bill of complaint[45] in the Supreme Court of the United States against the State of Wyoming, in which Nebraska asked the Court:

> (1) "To require that Wyoming, in the administration of waters of the North Platte River, should deny water to her direct-flow water users having junior priorities when water is needed by senior Nebraska appropriators;
>
> (2) "To require that Wyoming prevent her appropriators for storage from taking water for such purposes when the water is needed by senior Nebraska appropriators;
>
> (3) "To prevent Wyoming from allocating to a new irrigation project, known as the Casper-Alcova Project, a 1904 priority, when, as Nebraska claims, it is only entitled to a 1934 priority, and many Nebraska projects of 1904 priority and later would be deprived of water in the administration of the stream with a 1904 priority of the Casper-Alcova Project;
>
> (4) "As an incident to said direct relief, and in order to provide an exact basis for a decree covering the administration of the stream in the future to fix and determine the respective priorities on the stream of Nebraska and Wyoming appropriators."

In its demurrer and motion to dismiss, Wyoming claimed that Colorado, and the Secretary of the Interior, because of the North Platte Federal Reclamation Project, are necessary parties to this action.

The State of Nebraska, in its answer to Wyoming's motion, asserted that, since no relief is asked by complainant against the State of Colorado, and since the State of Colorado has no interest in the relief asked, against the State of Wyoming, or in the controversy between the State of Nebraska and the State of Wyoming, the State of Colorado is not a necessary party to the action because the States of Nebraska and Wyoming represent the interests of their respective water users under the Federal Reclamation Project; but upon Wyoming's amended complaint, the Court required that Colorado be made a party to the suit. On May 4, 1936, Colorado filed its answer and cross bill, in which issue was taken with the claims of both Nebraska and Wyoming, and in which Colorado establishes its own claims to an equitable division of the waters of the North Platte River.

The fundamental contentions with respect to the ownership and use of the waters of this interstate stream are as follows:

Nebraska contends that priority of appropriation shall prevail regardless of State lines. Wyoming contends that such a doctrine in the present case, due to the peculiarities of the river, would inevitably result in an unwarranted and wasteful use of the water supplies of the river, while Colorado bases its contentions upon "equitable apportionment" between the three States, regardless of priority of appropriation or riparian rights.

The Court appointed a Master to hear testimony, which began in the Summer of 1936. Nebraska submitted voluminous testimony, which has been subjected to cross-examination. It is now (1939) anticipated that several years will elapse before Colorado and Wyoming have concluded their testimony and the case is presented to the Court for final determination.

---

[45] Wyoming *vs.* Colorado, 295 U. S. 40.

Federal Intervention in Nebraska vs. Wyoming and Colorado, North Platte River Interstate Suit.—On June 15, 1938, the Department of Justice filed its petition for intervention in the pending interstate river suit in the case of Nebraska *vs.* Wyoming, and Colorado an impleaded defendant, over the waters of the North Platte River. In the brief, the petition makes two distinct claims with reference to North Platte River water:

(1) Federal ownership of all the waters of the North Platte River (subject to vested rights), under the reserve powers of the Federal Government (this of course includes all unappropriated water); and,

(2) Federal ownership of such water as has been acquired under State laws and in conformity with Section 8 of the Reclamation Act.

It is inconceivable that both contentions can be maintained in the pending suit, and it is believed that the United States will have to elect "which horse it will ride."

In the ruling earlier in this case,[17] on Wyoming's motion to dismiss on the ground that the Secretary of the Interior had not been made a party defendant, although a holder of appropriations from the North Platte River, the United States Supreme Court had said,

> "The motion asserts that the Secretary of the Interior is an indispensable party. The bill alleges, and we know as a matter of law, that the Secretary and his agents, acting by authority of the Reclamation Act and supplementary legislation, must obtain permits and priorities for the use of water from the State of Wyoming in the same manner as a private appropriator or an irrigation district formed under the state law. His rights can rise no higher than those of Wyoming, and an adjudication of the defendants' rights will necessarily bind him. Wyoming will stand in judgment for him as for any other appropriator in that state. He is not a necessary party."

Since the Court declined to allow individuals as appropriators to intervene in that suit and had also declined to allow individuals as appropriators to intervene as parties defendant in the pending Colorado *vs.* Kansas suit in that Court, it would seem that the United States has no greater standing as an appropriator or party in interstate litigation. Answers to the petition were filed by Nebraska and Wyoming on July 14, 1938, and by Colorado on August 29, the Court having extended the date for filing to September 1.

Suit over Return Waters from the North Platte Government Project on the North Platte River Between Whalen Dam and Bridgeport, Nebr.—In February, 1938, the Attorney General of the United States filed suit in the Federal District Court in the North Platte Division, claiming all the return flow from the lands of the North Platte Government Project, consisting of about 225 000 acres, served by the Interstate, North Port, and Fort Laramie Canals, of which about 200 000 acres are now irrigated. The suit is recorded as "United States *vs.* Tilley, Willis, and the Farmers Irrigation District."[46] The Farmers

---

[46] United States *vs.* Tilley, Willis, and the Farmers Irrigation District; in the U. S. Dist. Court of Nebraska (not yet reported).

Irrigation District is a mutual organization in Nebraska, which owns and operates the Tri-state Canal, diverting water from the North Platte River just below the Wyoming-Nebraska State line. This District was made a party to the proceeding for the reason that it has a Warren Act contract with the U. S. Bureau of Reclamation for the delivery of as much as 100 000 acre-ft of storage water per yr out of the Government-owned Pathfinder Reservoir located on the North Platte River in Wyoming. This contract contains a clause whereby the Bureau of Reclamation may substitute return flow water from the North Platte Government Project lands in lieu of storage water from the Pathfinder Reservoir.

The suit was brought against water officials, the State Engineer, and the Chief of the Bureau of Irrigation, Water Power and Drainage, of Nebraska, on the question of the ownership of return flow from the Government Project lands which reaches and is diverted by the Tri-state Canal for the North Port unit of the North Platte Government Project.

State officials of Nebraska have always taken the position that return flow waters resulting from irrigation belonged to the public streams of the State into which they would naturally flow, and are subject to distribution to appropriators along the stream in their relative orders of priority. The suit in question is based upon conditions as of May 8 to May 20, 1936, during which period there was insufficient natural river flow to supply appropriators in Nebraska with priorities senior to December 6, 1904, the date of the priority of the Government canals. This condition caused the Nebraska water officials to deny water from the natural flow of the river to the North Port unit of the Government project. The quantity of return flow available to the Tri-state Canal during the irrigation season amounts to about 75 000 acre-ft. Should the Bureau of Reclamation get a favorable decision in the pending suit, the Bureau would then be in a position to claim control of all the return flow from the North Platte Government Project lands, which amounts to approximately 500 000 acre-ft per yr, of which 250 000 acre-ft returns to the North Platte River during the irrigation season.

In its bill of complaint, the United States contends for all return flow from the North Platte Government Project.

Should the United States, through the Bureau of Reclamation, secure control and ownership of the return flow to the North Platte River, resulting from the irrigation of the lands under the Government Project, it is probable that the decision would be cited in the future as establishing a legal basis applicable to return waters from other Government projects. For this reason, the decision is awaited with much interest and concern.

The return flows from the lands under the North Platte Government Project, plus return flows from privately owned canals between the Whalen Diversion Dam in eastern Wyoming, owned by the Government, and Bridgeport, are equal to about 850 000 acre-ft per yr. That portion of this return flow which reaches the river during the irrigation period relieves the upper river from the necessity of supplying a large quantity of water for canals and storage units of the North Platte Government Project, approximating 200 000 acre-ft per yr. It is alleged, therefore, that the North Platte Government

Project is a direct beneficiary of the return flows to the North Platte River, not only from the North Platte Government Project lands, but also from privately owned canals. If control of the return flow is secured by the Federal Government, it is alleged that senior Nebraska appropriators will be deprived of a portion of the waters they are now receiving, which in turn will have an adverse effect upon the natural water supplies in the upper reaches of the river.

Nebraska alleges that, in the late summer months, the upper river flow diminishes to such an extent that Nebraska canals will receive less water during the late summer period than under the present conditions of stream flow. It is also alleged that the United States has never acquired, through State permits, right to the use of the return flow waters in controversy, but in lieu thereof has asserted claim to the same by posting notices in 1912 on various tributaries of the North Platte River, where the return flow waters have accumulated.

Cases Decided by Federal District Courts

Pioneer Irrigation Company vs. Weiland, State Engineer of Colorado, et al.—In 1922, water users in Nebraska under the Pioneer Ditch (which heads on the North Fork of the Republican River in Colorado a few miles above the Colorado-Nebraska State line) brought suit[47] in the Federal District Court for the District of Colorado against water users under the same ditch in Colorado, including State Engineer John E. Field, M. Am. Soc. C. E., who was later succeeded by A. A. Weiland, M. Am. Soc. C. E. Substantially one-third of the water diverted by this ditch is used in Colorado and two-thirds in Nebraska. The allegations in this case were to the effect that the water users in Nebraska under the Pioneer Ditch were being deprived of their rightful share of water by users in Colorado.

The Federal District Court found that the water users in Nebraska must receive the same treatment as if the canal and the irrigators thereunder were located entirely within the State of Colorado, and enjoined the water users in Colorado and its State officials from any action which would not be consonant with such requirement. The decision of the Federal District Court was appealed to the U. S. Circuit Court of Appeals, which upheld the decision of the District Court. From this decision, an appeal was taken to the U. S. Supreme Court, which confirmed the decision of the lower Federal Courts on June 5, 1922, and the waters diverted by the Pioneer Ditch have been distributed in accordance with the mandate of the Court since that date.

Action Brought to Restrain the City of New York, N. Y., from Maintaining a Dam on the West Branch of the Byram River.—It was held[48] that the State of New York, in its exercise of power of eminent domain, could not enable the City of New York to erect, within the limits of the State, a dam across an unnavigable river, having its source in New York, and divert the water for use in the City of New York, thus diminishing the flow and injuring riparian rights in Connecticut. The Court further held that right of complainants to use of water in its natural flow was not a mere easement, but was a right inseparably annexed to the soil itself.

---

[47] Pioneer Irrigation Co. *vs.* John E. Field and A. A. Weiland as State Engineers of the State of Colorado, 238 Fed. 519; 259 U. S. 498 (1922); 42 S. Ct. 568.

[48] Pine *vs.* New York City, 112 Fed. 98; 185 U. S. 93; 22 S. Ct. Rept. 592 (1902).

Action Brought by Citizens of Wyoming against Citizens of Colorado to Enjoin Diversion of Water from Sand Creek within the State of Colorado.—It was held[49] that complainants who were in possession of the water of an interstate stream for irrigation purposes in Wyoming were entitled to an injunction restraining the diversion of water of a stream flowing from Colorado into Wyoming by subsequent appropriators, who diverted one-half of the water into another stream, entirely different in its course, for irrigation of lands in Colorado.

Action Brought by Citizens of State of Nevada to Enjoin Diversions of Waters of West Fork of Carson River by Citizens of State of California.—In this case[50] it appeared that the doctrine of appropriation prevailed in Nevada whereas common law governing riparian rights was in effect in California. It was held that riparian owners in California and appropriators in Nevada of water of streams flowing from California into Nevada each had a right to have a reasonable apportionment of the water during the dry season, and a decree was made giving each party alternately the right to use the water for a certain number of days during the dry season, ordering the up-stream owners to return the surplus to the river.

Howell vs. Johnson[51] *and Morris vs. Bean.*[52]—In these cases the Court held to the following effect: One who has acquired a right to the water of an interstate stream by prior appropriation, in accordance with the laws of the State where it was made, is protected in such right against subsequent appropriations, although the latter withdrew the water within the limits of a different State.

Rickey Land and Cattle Company vs. Miller and Lux.[53]—Controversy arose in the case of Rickey Land and Cattle Company *vs.* Miller and Lux as to respective rights of the parties to the waters of the Walker River in the States of Nevada and California. It was held that the Federal Court in Nevada, and the California State Courts, had concurrent jurisdiction in the matter, and whichever Court first acquired jurisdiction was entitled to proceed to final determination without interference from the other, this action being *in personam* and affecting private rights only.

Morris vs. Bean.—This case[54] involved respective rights of the parties to the waters of Sage Creek in Montana and Wyoming. It was held that, subject to such rights as the Supreme Court might decide that the States have, and to vested rights, each State had full legislative power over Sage Creek while it flows within such State. In the absence of legislation, it will be assumed that the States were willing to ignore boundaries and allowed the same rights to be acquired from outside the State that could be acquired from within.

Right of States to Settle Interstate Differences by Compacts

The right of States to divide the waters of interstate streams by the compact method was definitely determined by the U. S. Supreme Court in a decision handed down on April 25, 1938. The validity of an interstate compact, which allocated the equitable portion of the river flow to which each of the compacting parties and its respective citizens were entitled, had been drawn directly in question.

In the decision written by Mr. Justice Brandeis, the Supreme Court held that a compact approved by Congress, which apportioned the waters of an interstate stream equitably between the two States, was binding upon the States and upon the citizens and officials of the States, even when neither of the States was a party to the suit.[28]

The La Plata River and Cherry Creek Ditch Company appropriated irrigation waters out of the La Plata River in southwestern Colorado, and thereafter in a water adjudication proceeding in the District Court of La Plata County, Colorado, received a decree for 41.5 cu ft per sec of water with date as of June 2, 1890. Under the Colorado constitution and statutes, relative dates of appropriation determine the rights of water users. The ditch company in this case was given the sixth priority in Water District No. 33. The five prior rights on the stream had been decreed a total of 19 cu ft per sec of water.

Residents of New Mexico with lands capable of being irrigated from the same river had also applied the waters of that stream to a beneficial use, and in 1921 when the citizens of New Mexico protested that Colorado water users were taking so much of the stream flow that the lands in the lower State were deprived of their necessary supply, the two States determined to apportion the water equitably by exercising the power to compact, reserved to the States under the provisions of the Constitution of the United States. Acts were passed by the Legislatures of the two States, authorizing the appointment of commissioners to apportion the waters of the La Plata River equitably between them, and specifically providing that such agreement should become binding only when ratified and approved by the Legislatures of the two States and consented to by Act of Congress.

Thereafter, the Commissioners for Colorado and New Mexico executed the La Plata River Compact, and it was duly ratified by the Legislatures of the two States and consented to by Act of Congress.[55]

In the Spring of 1928, during a severe water shortage in the river, the flow became so scant that the two State Engineers agreed that the most beneficial use of the water could be obtained by permitting each State to enjoy the entire flow in alternating periods of 10 days. On a day in June, 1928, a Deputy State Engineer, under direction of the State Engineer, closed the head-gate of the La Plata River and Cherry Creek Ditch, as well as the head-gates of all other ditches in the State of Colorado, in order to permit the entire flow to go across the interstate line into New Mexico. At the time this action was taken, there were only 57 cu ft per sec of water in the stream in Colorado.

In order to give the La Plata River and Cherry Creek Ditch Company the water to which it claimed to be entitled under its Colorado decree, it would have been necessary to curtail deliveries to New Mexico greatly, due to losses in transit.

---

[55] Hinderlider *et al. vs.* La Plata River and Cherry Creek Ditch Company (see Compact, p. 64).

The ditch company immediately brought suit to enjoin the State Engineer of Colorado and his subordinates from closing its head-gate, charging that there was water in the stream to which it was entitled under its decree, and that his administration of the stream was contrary to the laws of Colorado and the Court decrees under which the ditch company had acquired its rights.

The defense of the water officials was based upon the proposition that the head-gate was closed in enforcement of the provisions of the La Plata River Compact. The ditch company replied that the State water-administrative officials had ignored Court decrees entirely and were claiming the right to distribute, prorate, and rotate the waters without regard to the decrees of the laws of Colorado.

The case was first tried in the local District Court in May, 1929, although the decision was not rendered until June, 1930. The trial Court dismissed the complaint and held that the State water-administrative officials were distributing the river flow in conformity with the Compact, and that no rights of the ditch company had been violated. The ditch company prosecuted a writ of error to the Colorado State Supreme Court, which reversed the lower Court for the reason that a vested property right of the ditch company had been taken without due process of law and without just compensation, contrary to the provisions of the State and Federal Constitutions.[56]

In discussing the right to rotate the use of the entire flow in alternate periods, the Court said that "if private rights may be stripped from the citizen by state 'compacts,' by legislative fiat, by commissioners, by the uncontrolled discretion of state engineers, then 'due process' is dead in Colorado." Again the decision says: "It [the Compact] is a mere compromise of presumably conflicting claims, a trading therein, in which the property of citizens is bartered without notice or hearing, and with no regard to vested rights."

The Attorney General of Colorado then took an appeal from the decision of the Colorado State Supreme Court to the U. S. Supreme Court, but the latter tribunal refused to take jurisdiction on the ground that at that time there was no final judgment in the trial Court from which the appeal could be taken.[57]

Thereafter the matter was returned to the trial Court, where a new judge was presiding and, upon a stipulation that the evidence in the first trial should be considered as the record in the second hearing, a judgment was entered in harmony with the views expressed by the State Supreme Court. This commanded the water-administrative officials to regulate the head-gate of the ditch company so as to permit it to receive the water, to which it was entitled under its decree from the State Court, at all times, without reference to the provisions of the Compact.

The water-administrative officials then prosecuted a writ of error to the Supreme Court of the State of Colorado which reaffirmed its former decision, with certain explanatory observations and statements tending to strengthen and support its original position.[58] The case then went to the Supreme Court of the United States, on appeal a second time, and was argued before that Court on February 10 and February 11, 1938.

---

[56] Hinderlider *et al. vs.* La Plata River Cherry Creek Ditch Company, 93 Colorado 128.

[57] Hinderlider *et al. vs.* La Plata River Cherry Creek Ditch Company, 291 U. S. 650, 54 S. Ct. Rept. 557.

Colorado's Constitution dedicates the use of all unappropriated waters in the natural streams of the State to the people, and expressly declares that the water is the property of the public. Under this doctrine, Colorado had always claimed the right to divert the entire flow of any stream rising within its borders, regardless of the claims of sister States and their residents. In the cases of Kansas *vs.* Colorado[59] and Wyoming *vs.* Colorado,[60] the Supreme Court of the United States held that this constitutional provision did not give to Colorado the ownership of all the water flowing within its borders, but expressly announced the doctrine that every State upon an interstate stream is the owner of an equitable portion of the flow of the stream, which the other States are bound to recognize and respect. This doctrine has been announced by the Supreme Court on numerous occasions since that time.

The defendant water-administrative officials took the position that the equitable apportionment which had been effected by the La Plata Compact determined the limit of the water to which Colorado and its citizens were entitled, and that the title of any water users in Colorado was necessarily limited by the rights of New Mexico. In other words, it was contended that no vested right of any Colorado water user was invaded when New Mexico received only the quantity to which it was entitled by the terms of the Compact. Of necessity, water delivered to New Mexico under the terms of the Compact was water which no Colorado appropriator might acquire under a decree from a Colorado Court.

The ditch company contended, and the State Supreme Court took the position, that the entry of a decree in a water-adjudication proceeding by a Colorado Court vested in the claimant a property right which could be taken away only after an action in Court with the payment of just compensation therefor. The United States Supreme Court held that no property of the ditch company had been taken, and no vested right had been violated.

Mr. Justice Brandeis said:

> "As Colorado possessed the right only to an equitable share of the water in the stream, the decree of January 12, 1898, in the Colorado water proceeding did not award to the ditch company any right greater than the equitable share. Hence the apportionment made by the compact cannot have taken from the ditch company any vested right unless there was in the proceedings leading up to the compact or in its application some vitiating infirmity. No such infirmity or illegality has been shown."

In answer to the charge that rotation constituted a taking of a vested right, the water-administrative officials asserted that, in time of scarcity when evaporation and transportation losses are heavy, greater benefits attend the diversion of a larger body of water over a given period than the diversion of half the quantity over twice that period. On this proposition, the U. S. Supreme Court held that the delegation to the State Engineers of the authority to determine when the water should be rotated was a matter of detail clearly within the constitutional power.

---

[58] Hinderlider *et al. vs.* La Plata River Cherry Creek Ditch Company, 101 Colorado 73.

[59] Kansas *vs.* Colorado, 206 U. S. 100.

[60] Wyoming *vs.* Colorado, 259 U. S. 494.

The Supreme Court re-announced the doctrine that no State may divert all the water of a stream without regard to the injury or prejudice it may work upon the down-stream State. It said also that the compact adapts the age-old treaty-making power of independent sovereign nations to the union of sovereign States, and although the equitable rights of the States might have been determined in an original suit in that Court, the result of the exercise of the compacting power is equally effective.

The Supreme Court held that a division of the water of a stream, whether by compact with the consent of Congress, or by decree of the Supreme Court, is binding upon the citizens of each State. This part of the decision was based upon a number of early decisions in which questions arose over the location of the boundaries between the original States and had been settled by compacts or boundary conventions. Thereafter, when private parties claimed title to the same land under patents from different States, the Supreme Court upheld the boundary conventions and said that the title claimed under a patent from a State which had no title failed because of an intrinsic defect in the title of the State.

An interesting side-light on the legal phases of the question arose from the fact that the water officials had claimed that the Compact, when consented to by an Act of Congress, became a Federal statute, and that under Section 237 (*a*) of the Judicial Code they had the right to take the case to the Supreme Court on appeal. The U. S. Supreme Court denied this claim and dismissed the appeal, but held that the injunction from administering the Compact denied an important claim under the Constitution which may be reviewed by certiorari under Section 237 (*b*). The Court held that jurisdiction over controversies concerning rights in interstate streams is not different from those concerning boundaries, and whether the water of an interstate stream must be apportioned between the two States is a question of Federal common law upon which neither the statutes nor the decisions of either State can be conclusive. Likewise the Court held that it had jurisdiction to determine the validity and effect of the Compact even if New Mexico and Colorado were not parties to the suit and could not be made parties.

The State of Colorado was the pioneer in the movement to settle disputes over irrigation waters between States by the Compact method. The La Plata is a small stream with a comparatively short run-off, but all of the questions involved in the determination of the validity and effect of such a compact were presented in this case. For nearly ten years the matter was litigated in the Courts, while the validity of all of Colorado's interstate compacts hung in the balance.

Now (1939) it has been judicially determined that the States, through commissioners conversant with the problems of irrigation, may divide the waters of western rivers equitably and intelligently, and thus long drawn-out and expensive litigation possibly may be avoided. With the relevant facts at hand, any group of fair-minded men may make a compact that will protect and preserve the interests of the people fairly and adequately.

INTERSTATE COMPACTS

Settlement of controversies between States, in regard to the use of waters of interstate streams, has been effected in a number of cases, notably in the arid region, by compacts between the States involved. Such compacts are permitted under the Constitution, but must be ratified by the Legislatures of the compacting States and approved by the Congress of the United States before becoming effective.

There appears to be a disagreement between authorities concerning the necessity for the compacting States first to obtain the consent of Congress before entering into negotiations. Many authorities take the position that prior consent of the Congress is not essential when the compact is later approved by Congress. Congress may enforce any conditions it deems desirable for conserving the interests of the Federal Government prior to approving any interstate compact. In each case involving the Western States, the President has designated a representative of the United States to participate in the negotiations between States, and this representative is usually designated by the representatives of the States to act as chairman of the Interstate Commission.

The Weeks Act of March 1, 1911, provides[61]

> "Be it enacted by the Senate and the House of Representatives of the United States of America, in Congress assembled, that the consent of the Congress of the United States is hereby given to each of the several states of the Union to enter into any agreement or compact, not in conflict with any law of the United States, with any other state or states, for the purpose of conserving the forests and water supply of the states entering into such agreement or compact."

Likewise, the Omnibus Flood Control Act of 1936 authorized the States to enter into compacts under certain conditions. At times the Supreme Court of the United States has recommended solution of interstate problems by means of interstate treaties or compacts. However, comparatively few of the States have availed themselves of this very effective method for the settlement of their differences with respect to the waters of an interstate stream. A survey of all of the forty-eight States discloses that those which have no compacts or interstate agreements concerning the waters of an interstate stream system, nor litigation over such waters, are Alabama, Arkansas, Florida, Georgia, Iowa, Maine, Mississippi, Missouri, and Rhode Island. In all the other thirty-nine States, there has been litigation between one or more States.

According to the report of the National Resources Committee of December, 1935, fifty-seven interstate compacts have been authorized, of which thirty-four have finally become effective through State ratification. In addition, thirteen compacts have been authorized by one or more States without Congressional authority or approval. The larger number of these compacts, however, had to do with such matters as State boundaries, cessions of territory, jurisdiction over boundary waters, uniformity of legislation, interstate accounting, utility regulation, and prevention of crime.

---

[61] Weeks Act of March 1, 1911, 36 Stat. L. 961.

Of the forty-four compacts to which Congress has given its approval since 1900, thirty have been effected within the period since 1918. In this connection, the Federal Government has not been content with a constitutional rôle of passive approbation, as disclosed by the Weeks Act. Congress may take the rôle of stimulator of interstate compacts in a particular field by a general authorization for the States to enter into such agreements, but even in the case of more specific authorization (as in the statute for the apportionment of the waters of the Columbia River between Washington, Idaho, Oregon, and Montana) Congress has established the principle of Federal participation in the negotiations. There has been no State action as yet (1939) under the provisions of the Weeks Act, and apparently Congress has been willing to approve in advance, and without serious delay, the negotiation of compacts relating to a particular question or region. As heretofore stated, it appears that the participation by Congress may precede or follow the stage of negotiations. There are examples of both types of procedure.

Some students of the compact method, as a device for the adjustment of disputes over interstate streams, have declared what they conceive as uncertainties associated with its use as a means for securing State co-operation in the development of streams, in view of the existing conflicts of law, among the States, relating to water rights. These uncertainties, they contend, are increased because of the fact that there is no clear line that determines the ultimate application of Federal authority over navigable streams, or the regulation of the source of supply of such streams. The question of the authority of the Federal Power Commission to pass upon the rights of States to enter into compacts concerning the use of certain streams in the Eastern States has now been injected into the problem (Connecticut, Merrimac, and Delaware River Compacts).

Colorado River Compact.—This Compact, providing for the equitable division of the waters of the Colorado River system in the United States, was signed by the commissioners representing the States of Arizona, California, Colorado, Nevada, New Mexico, Utah, and Wyoming at Santa Fe, N. Mex., on November 24, 1922, and was thereafter ratified by Wyoming on February 25, 1925, by Colorado on February 26, 1925, by Utah on March 13, 1925, by New Mexico on March 17, 1925, by Nevada on March 18, 1925, and by California on April 8, 1925, and promulgated by the President on July 25, 1925. Arizona has declined to ratify the Compact to date (1939) or, by self-limitation through legislative action, to subordinate itself to the provisions of the Compact, and has asserted that the assured and planned projects in California would absorb all of the additional water made available to the Lower Basin States by the Compact.

The Compact apportions in perpetuity, from the Colorado River System to the Upper Basin and to the Lower Basin, respectively, the exclusive beneficial consumptive use of 7 500 000 acre-ft of water per yr. The dividing line between the basins is at Lee Ferry, Ariz., 1 mile below the mouth of the Paria River. An additional 1 000 000 acre-ft per yr are apportioned to the Lower Basin for beneficial consumptive use when the first 7 500 000 acre-ft have been consumed.

If the United States should hereafter recognize in Mexico, as a matter of international comity, any right to the use of the waters of the Colorado River system, such waters shall be supplied from surplus waters over and above the aforementioned apportionments. If such surplus waters are insufficient for this purpose, the deficiency shall be borne equally by the Upper and Lower Basins.

The Compact provides that the States of the Upper Division (Colorado, New Mexico, Utah, and Wyoming—not identical with "Upper Basin") will not cause the flow of the river at Lee Ferry to be depleted below an aggregate of 75 000 000 acre-ft for any period of ten consecutive years reckoned in continuing progressive series. Waters not thus apportioned may be apportioned equitably for beneficial use any time after October 1, 1963.

The ratification of this Compact was followed by the passage in 1928 of the Boulder Canyon Project Act which provided for the construction of the Hoover Dam and the All-American Canal. It also requires California to limit, by statute, her portion of the beneficial consumptive use of the 7 500 000 acre-ft, apportioned to the Lower Basin, to 4 400 000 acre-ft. This was done later by legislative enactment.[62]

The Compact makes the use of water throughout the Colorado River Basin for the generation of power subservient to that for domestic and agricultural purposes.

Further comment concerning litigation between Arizona and California, and the other States of the Colorado River Basin, relating to the fulfilling of the provisions of the Boulder Canyon Project Act, has been made in greater detail herein under the heading "Interstate Litigation."

La Plata River Compact.—This Compact between Colorado and New Mexico, dividing the waters of the La Plata River in southwestern Colorado and northwestern New Mexico, was signed at Santa Fe by the commissioners representing the two States on November 27, 1922, following which Colorado ratified the Compact on April 13, 1923, and New Mexico on February 7, 1923. The Compact was approved by the Congress of the United States on January 25, 1925, and promulgated by the President on January 29, 1925.

In the negotiation of this Compact, no regard was given to the relative dates of priority and decreed quantities of water in the two States, the constitutions of which specifically adopt the doctrine of appropriation rather than the doctrine of riparian ownership, the attempt and intention being to apportion the waters of the La Plata River equitably between the two States. It so happens that practically all of the firm water produced by the river during the critical period of the irrigation season is claimed under Court decrees in New Mexico. Due to their relative geographical locations on the stream, later appropriations of water in Colorado exhausted practically the entire dependable stream flow, which resulted in a threat on the part of New Mexico to ask for relief against Colorado in the Supreme Court of the United States, which was the basis for the consummation of the Compact.

The Compact provides (*a*) that at all times between the first day of December and the fifteenth day of the succeeding February, each State shall have the unrestricted right to the use of all the waters originating in such State, or flowing within its borders, (*b*) that at all other times each State shall have the unrestricted right to the use of all the waters within its boundaries on each day when the daily flow at the Colorado-New Mexico State line is 100 cu ft per sec or more, (*c*) that on all other days Colorado shall deliver at the Colorado-New Mexico State line, for beneficial consumptive uses in New Mexico upon demand of New Mexico, a quantity of water equivalent to one-half of the mean daily flow on the preceding day at the Hesperus gaging station, situated about 33 miles above the interstate line, but not to exceed 100 cu ft per sec.

---

[62] Assembly Bill No. 1070, California Legislature, passed March 4, 1929.

From the foregoing, it will be noted that Colorado must bear the burden of the loss of water in transit when delivering one-half of the flow of the river down to the State line. This requirement has proved to be a serious burden at times since the initiation of the administration of the Compact in 1925. The Compact also provides that the total quantity of water in the river may be rotated between the States for predetermined periods of time by the State Engineers of the two States for the more efficient use of the common supply. This practice has been in effect each year during periods of low stream flow since 1924. As a result of this practice of rotation, the La Plata River and Cherry Creek Ditch, with priority No. 6 on the La Plata River in Colorado, sought to enjoin the water officials of Colorado in making such rotations, which had the effect of depriving that ditch of all water during such periods of rotation, alleging that such action on the part of the water officials was unconstitutional, since it had the effect of taking away property rights without due process of law. This suit (discussed at greater length under the subject of "Interstate River Litigation") resulted in the noted case of Hinderlider *vs.* La Plata River and Cherry Creek Ditch Company, just decided April 25, 1938, by the Supreme Court of the United States.

South Platte River Compact.—This Compact between Colorado and Nebraska was signed by the commissioners representing the two States on April 27, 1923. Thereafter it was ratified by Nebraska on May 23, 1923, and by Colorado on February 26, 1925, and was approved by the Congress of the United States on March 8, 1926, and promulgated by the President on March 9, 1926.

This Compact provides that, between the first day of April and the fifteenth day of October of each year, Colorado shall have the use of the entire flow of the South Platte River, with the provision for full recognition of the right of the Western Ditch, which heads on the South Platte River 4 miles east of the Colorado-Nebraska line, to divert as much as 120 cu ft of water per sec under its date of priority of June 14, 1897.

The Compact also provides that at all times between the 15th day of October and the 1st day of the succeeding April, Colorado shall have the full and uninterrupted use of the water of the river flowing within the borders of the State, provided, however, that Nebraska and its agents shall have the right to construct a canal, heading on the river near Ovid, Colo., with the recognized date of priority as of December 17, 1921, to divert as much as 500 cu ft per sec during the period of October 15th to April 1st, for the irrigation of lands in Nebraska. This provision is subject, however, to a prior reservation of 35 000 acre-ft of water per yr for future uses in Water District No. 64, which embraces the lower section of the river in Colorado.

The Compact also covers several minor features, such as the use of the waters of Lodgepole Creek (a small tributary of the South Platte River which rises in southern Nebraska and flows into Colorado), together with matters of administration, which are placed in the hands of the State Engineers of the two States. This Compact does not change the former administration of the waters of the South Platte River in Colorado, but does remove the shadow of future claims by the State of Nebraska against existing uses of water from the South Platte River in Colorado, and possible litigation in this connection.

This Compact has been administered since the Spring of 1926, under rules promulgated by the State Engineers of the two States, without the least friction, and may be considered to be one of the outstanding examples of this character on record.

It may be of interest, in passing, to note that, in an interstate suit between Nebraska and Wyoming[17] over the waters of the North Platte River (in which suit Colorado is made an impleaded defendant), the Attorney General of Nebraska has acknowledged the validity of the South Platte River Compact between Colorado and Nebraska, and that Nebraska fully intends to maintain its obligations faithfully under the Compact. Although it does not attack the validity of the Compact, Wyoming has expressed the view that, had Nebraska not entered into the Compact with Colorado (by the terms of which Nebraska foregoes the right to the use of a larger share of the waters of the South Platte River than that to which she may have been entitled), any burden which may fall upon Wyoming as a result of an adverse decision in the pending North Platte River suit would be of less magnitude than it would have been except for the South Platte River Compact between Colorado and Nebraska.

Rio Grande Compact.—The States of Colorado, New Mexico, and Texas have been conducting negotiations since before 1929 with a view to adjusting their respective claims on the waters of the Rio Grande above Fort Quitman. This interstate problem has "hung like a pall" over the water users of the upper Rio Grande basin in the three States for more than 40 yr. As a result of previous negotiations, the three States entered into a temporary Compact designed as a truce to maintain the *status quo* on the upper river on February 12, 1929. This Compact was ratified by Colorado on April 9, 1929, by New Mexico on March 9, 1929, and by Texas on May 2, 1929. Thereafter it was approved by the Congress of the United States on June 1, 1930, and promulgated by the President on June 17, 1930.

This temporary Compact, which covered a period of 5 yr, provided for the equitable apportionment, among the three States, of the waters of the Rio Grande above Fort Quitman. It also declared that, since the United States Government had disposed of 60 000 acre-ft of water per yr in perpetuity to the Republic of Mexico, in the settlement of claims preferred by that nation against the United States, it follows as a corollary that the United States should defray the cost of the discharge of any obligation thus assumed; as, for example, the repayment to the three States for the loss of water taken from these States in settlement of the Federal Government's assumed obligation to the Republic of Mexico. For the purpose of meeting this obligation, at least in part, and for the economic development and conservation of the waters of the Rio Grande Basin, and to aid in the settlement of the interstate controversy, the States agreed in this temporary compact that: (*a*) It is of primary importance that the area in Colorado, known as the Closed Basin, be drained; (*b*) that the water thus recovered be added to the flow of the river; and that, in this connection, a reservoir for equating the flow be constructed near the Colorado-New Mexico State line—all at the expense of the Federal Government.

The temporary Compact also provided that, until the construction of the aforementioned Closed Basin Drain and the State line reservoir, but not subsequent to June 1, 1935, the date fixed for the expiration of the Compact, Colorado would not cause, or permit, the water supply at the Colorado-New Mexico State line to be impaired by new or increased diversions or storage within the State of Colorado, unless and until such depletion was offset by increased drainage return.

The temporary Compact also provided for the maintenance of the then *status quo* on the Rio Grande in the three States above Fort Quitman, and that no development in either State during the life of the Compact should have the effect of establishing any claim upon the river or its tributaries as against the rights, or to the prejudice, of any of the signatory States.

Negotiations were continued from time to time during the 5-yr life of this temporary Compact, looking to the consummation of a permanent Compact, without tangible results. The Legislatures of the three States, by unanimous agreement, extended the life of the Compact to June 1, 1937, and again until October 1, 1937, when the temporary Compact was allowed to expire. Prior to the latter date, however, the Commissioners duly appointed by the Governors of the three States (for Colorado, M. C. Hinderlider, M. Am. Soc. C. E.; for New Mexico, Thomas M. McClure, M. Am. Soc. C. E.; and for Texas, Mr. Frank B. Clayton), and a representative of the United States (S. O. Harper, M. Am. Soc. C. E.), continued with their negotiations for a permanent compact. On September 23, 1936, however, the President, by executive order, instructed the appropriate Federal agencies "* * * not to approve any application for a project involving the use of Rio Grande waters without securing from the National Resources Committee a prompt opinion on it from all relevant points of view." This executive order was based upon the assumption that further developments in the Rio Grande Basin above Fort Quitman might impair existing Federal investments, and also violate the terms of the temporary Rio Grande Compact, to which the Federal Government was a party. Following the issuance of the foregoing order, the three Interstate River Commissioners entered into an agreement with the National Resources Committee for a comprehensive and detailed survey of the land and water resources of the Upper Rio Grande Basin, present uses, deficiencies, surpluses, and future requirements, together with a determination of the feasibility of supplementing existing water resources of the basin through the importation of waters from the Colorado River Basin.

The investigation was conducted by the Water Resources Committee under the general supervision of the National Resources Committee, and under the immediate supervision of Harlan H. Barrows and Prof. Frank Adams, representing the Water Resources Committee, and N. C. Grover, M. Am. Soc. C. E., Chief Engineer of the United States Geological Survey, representing that Department. Separate phases of this investigation were allocated to the United States Bureau of Agricultural Engineering, the United States Geological Survey, United States Bureau of Reclamation, and United States Bureau of Plant Industry, the three States co-operating through their Interstate River Commissioners and State Engineers, and through financial assistance to the sum of $55 000. The major cost of the investigation, amounting to about $400 000, was borne by the National Resources Committee and various agencies of the Federal Government. This investigation, it is believed, was the most complete ever undertaken by the Federal Government in connection with an interstate stream. The investigation covered a period of about 1½ yr, and the results have been compiled in two volumes by the National Resources Committee.[63]

Following the conclusions of this investigation in the Summer of 1937, the Interstate River Commissioners and their advisers, after six different conferences at Santa Fe, finally concluded and signed, on March 18, 1938, a permanent Compact which divides the waters of the Rio Grande, equitably, above Fort Quitman, provides for their better regulation and conservation, and for the importation of waters to the basin from other drainage areas, and also for the recovery of waters from the Closed Basin area in Colorado, which are not now tributary to the Rio Grande. It is believed that this document —consummated after more than ten years of strenuous endeavor, under the most difficult conditions resulting from long and bitter opposition between the three States, and as a result of an international treaty and previous huge Federal investments in the lower basin—is an outstanding example of the ability of States and the Federal Government to adjust the most complicated problems arising out of the use of the waters of an interstate stream.

Briefly, the Rio Grande Compact accomplishes two major purposes:

(*a*) It protects the present uses of water in the three sections of the Rio Grande in Colorado, New Mexico, and Texas by setting up schedules of required delivery of water by Colorado at the Colorado-New Mexico State line, and by New Mexico at San Marcial, which is just above the Elephant Butte Reservoir, and by fixing the average annual releases from the Elephant Butte Reservoir for the irrigation of lands below that reservoir, and for use in Mexico, under the provisions of the international treaty.

(*b*) It permits the construction and operation of additional reservoirs in the basin above Elephant Butte Reservoir, for the purpose of regulating stream flow used at the present time (1939), and for capturing and making usable the water in the Upper Rio Grande Basin, which otherwise would spill from the Elephant Butte Reservoir and be lost.

---

[63] Regional Planning, Part VI, Upper Rio Grande, February, 1938, National Resources Committee.

The schedules of water deliveries are based upon the relation found to exist between the annual inflow into, and the outflow from, the San Luis Valley in Colorado for the years 1928 to 1937, both inclusive, and the relation between the flow at Otowi Bridge in Northern New Mexico and the flow at San Marcial for all years of record prior to 1930 (pre-middle Rio Grande Conservancy District period).

The Colorado-New Mexico State-line schedule of water deliveries is divided into two parts, one applying to the Conejos stream system, which is the largest tributary to the Rio Grande in Colorado, and the other to the Rio Grande proper above the Colorado-New Mexico State line. Required deliveries by the State of Colorado are taken as the sum of the required deliveries by the Conejos River System and by the Rio Grande proper, less 10 000 acre-ft annually. This schedule of deliveries will permit the use of water in Colorado which has been in force since the early Eighties, and will also permit the construction of large regulatory reservoirs in Colorado to make the seasonal stream flow more nearly parallel to the seasonal crop requirements and the elimination of distortion which has existed between these two natural factors in past years. Deliveries of water in exact accordance with the schedules are not required on an annual basis.

The Compact provides for a system of accounting whereby deviations from the deliveries required by the schedules are set up as debits or credits to the State making the deliveries. Such credits and debits are allowed to accumulate, subject to certain conditions. In the case of Colorado, departures of 100 000 acre-ft from the scheduled deliveries on the debit side in any one year, or an accumulated departure in the same amount, due to natural causes, are allowable. Deliveries of water in excess of the required scheduled deliveries are used to reduce debits and, in the absence of debits, are allowed to accumulate as credits. The credits may be reduced either by spill from Elephant Butte Reservoir, above El Paso, or by departures on the debit side in the delivery of water from the required scheduled deliveries. The Compact provides that debits may accumulate in any amount, so long as an equivalent quantity of water is held in storage in reservoirs to be constructed in New Mexico and Colorado in the future, provided that any portion of that water which otherwise would have spilled from Elephant Butte Reservoir becomes the property of the owners of the new reservoirs, and may be used in any way they see fit.

Deliveries of water by Colorado and New Mexico in excess of the quantities required by the schedule are accumulated in the Elephant Butte Reservoir as credits to the upper States, so long as the water remains in storage in Elephant Butte Reservoir. Should the stage of storage in Elephant Butte Reservoir cause an unusable spill of water from that reservoir, the water which is in storage to the credit of the upper States is reduced by the amount of such spill. In order that the area above Elephant Butte Reservoir shall have practically exclusive right to the consumption of the water which would otherwise spill from Elephant Butte Reservoir, the average annual release from that reservoir for beneficial, consumptive use is fixed at 790 000 acre-ft, which includes the 60 000 acre-ft required to be delivered to Mexico at El Paso under the existing international treaty. For the same reason, project storage in that reservoir is fixed by the Compact at 2 638 860 acre-ft, which was the original capacity of Elephant Butte Reservoir.

The Compact places the administration in the hands of the Rio Grande Compact Commission, consisting of the State Engineers of Colorado and New Mexico, and a representative to be appointed by the Governor of Texas. This Commission is authorized and required to maintain a number of gaging stations along the river system, and to compile and exchange the records obtained therefrom. Within certain limitations, the Commissioners, by unanimous action, may make minor modifications in the provisions of the Compact which later years may show to be desirable. Such modifications, however, must be made within the fundamental provisions of the Compact; and they become operative only when unanimous action has been ratified by the Legislatures of the States and consented to by the Congress of the United States. It was the intent of the drafters of the Compact that the actual administration of the waters of the river, to which each State is entitled, should be administered by the water officials of such State without the interference of a super-authority. The Compact also makes provisions for a representative of the United States Government on the Commission. This representative, however, will be without voting authority.

The Compact has been ratified by the Legislatures of the three States and by the Congress and is now (1939) in full force and effect.

Red River Compact Between Minnesota, North Dakota, and South Dakota (Signed June 23, 1937).—In the valley of the Red River of the North, a critical situation is being met through interstate co-operation between the States of Minnesota, North Dakota, and South Dakota. The problem of the Red River of the North is primarily a question of water. In the period from 1916 to 1919, the problem was one of floods, and from 1930 to 1935, one of drought, which threatened the water supplies of cities and farms. The successful meeting of these problems required interstate co-operation and Federal assistance. This assistance has been in the nature of a complete study of the problems by the Water Resources Committee of the National Resources Committee, in co-operation with the United States Corps of Engineers under a co-operative agreement between the Federal agencies and the Planning Boards of the respective States. The major problem was the conservation of water in lakes and reservoirs, and its release to stream channels which will provide a dependable water supply for the principal cities and other users. The plans include: (*a*) An increase in the effective storage in the lakes of the Otter Tail River System; (*b*) plans for a somewhat similar improvement in the use of Red Lake storage; and (*c*) plans for the construction of a large dam on the Cheyenne River and possibly dams on other streams on the Dakota side of the basin. In this connection, small dams are also proposed on various normally dry channels for the impoundment of stock water for rural needs. Another important phase of the plan is the improvement of stream channels for reducing losses of water in transit, which are now reported to be extremely high in this basin. The Compact provides for an interstate authority, with power to control the water resources of the area, and to levy limited assessments on the beneficiaries. However, the Minnesota Act that ratifies the Compact, excludes the Otter Tail Basin from the provisions of the Compact. The comprehensive report of the investigations leading up to the consummation of this Compact is included in the report of the National Resources Committee of August, 1937, on "Regional Planning."[64]

NEGOTIATIONS FOR INTERSTATE RIVER COMPACTS

Columbia River.—Negotiations concerning the use of the waters of the Columbia River were conducted for a number of years between the States of Montana, Oregon, and Washington, but it is understood that nothing tangible has resulted from such negotiations.

Yellowstone River.—Under authorization of the Congress, dated June 14, 1932, a Compact for the equitable apportionment of the waters of this river was signed by the representatives of Montana and Wyoming on February 6, 1935, which, however, was not acted upon by the Legislatures of the two States within the time limit fixed by Congress. It has been reported that the terms of this Compact would have been opposed by the United States Indian Service as a result of certain treaties with Indians involving the question of priority of use of the waters of this stream. Congress again authorized these two States to attempt to agree upon a compact by the Act of August 2, 1937.[65]

Control of the South Canadian River.—This Compact was signed on December 31, 1926, by the Commissioners representing the States of New Mexico, Oklahoma, and Texas. It was approved by New Mexico and Oklahoma, but never approved by Texas. By Act of the Legislature, New Mexico later withdrew its approval. The object of the Compact was to further the construction of the Conchas Flood Control Reservoir.

Congress has also authorized Compacts between New Mexico, Oklahoma, and Texas concerning the waters of the Canadian, Cimarron, and Rio Grande rivers. Under such authorization representatives of the three States agreed upon a Compact[66] concerning the waters of the Canadian River which was later ratified by the Legislatures of the States, but was vetoed by the Governor of Texas.

Congress also authorized a Compact between New Mexico and Oklahoma, covering the waters of the Cimarron River and other streams;[67] and Compacts between Colorado, Oklahoma, and Kansas, concerning the waters of the Arkansas River and other streams.[68] It is understood that controversial questions exist between Oklahoma and New Mexico, concerning the waters of the South Canadian and Cimarron rivers. Another interstate question in which the State of Oklahoma is interested concerns pollution from salt brines in the Kansas oil fields. It is understood that producers are co-operating in methods for correcting this trouble by returning brine extracted from oil wells back to salt-water strata outside the producing area.

---

[64] Regional Planning, Part V, "Red River of the North."

[65] Publication L. No. 237.

[66] Compact between New Mexico, Oklahoma, and Texas, 45 Stat. 1502.

[67] *Loc. cit.* 45 Stat. 1503.

[68] *Loc. cit.* 45 Stat. 1517.

Problems of an interstate nature between Oklahoma, Arkansas, and Louisiana concern retardation measures for the prevention of the flooding of both the Arkansas and Red rivers. Similar interstate problems between Texas and Oklahoma concern the flood waters of the Red River, which originates in Oklahoma. It appears that the solution of this problem may rest upon the construction of the large Denison Flood Control Reservoir on the Red River.

Compact to Divide Waters of the Snake River.—Congress authorized[69] the States of Idaho and Wyoming to enter into a Compact not later than January 1, 1934, providing for an equitable division and apportionment, between these States, of the waters of the Snake River and its tributaries. Pursuant to such authorization, the two States and the Federal Government appointed Commissioners who agreed upon a Compact. It was approved by the Legislature of Idaho in 1933, and later by the Lower House of the Legislature of Wyoming; but it failed to be approved in the Senate of that State, and later was withdrawn by its sponsors.

Authorization was given to these States by Congress,[70] and approved by the President May 16, 1938, to negotiate a new compact not later than January 1, 1940. Commissioners have not been appointed to date (1939).

Compact for Flood Control in the Connecticut and Merrimac River Basins.—Pursuant to the provisions of the Flood Control Act of 1936, establishing a national policy with respect to flood control throughout the United States, the States of Connecticut, Massachusetts, Vermont, and New Hampshire negotiated a Compact for the control of flood waters in the Connecticut River Basin, and the States of Massachusetts and New Hampshire negotiated a Compact for the control of floods in the Merrimac River Basin. Under the provisions of the Omnibus Flood Control Act of 1936, the Connecticut River Compact contemplates the construction, over a period of years, of a series of flood-control reservoirs upon tributaries of the Connecticut River to control approximately 21% of the drainage area. Of these, two could be constructed in Massachusetts, three in Vermont, and three in New Hampshire, at specified sites. The Compact provides for the creation of the Connecticut River Valley Flood Control Commission, consisting of twelve Commissioners, three to be chosen from each State. It is understood that the four States involved have made appropriations of funds required by the Compact for the States' obligations. Furthermore, the Compact had a favorable report by the Senate Committee on Commerce, by the United States Senate and by the Flood Control Committee of the House; but thus far (1939) it has failed to receive the approval of the Congress. Opposition to the approval of these Compacts by the Congress is reported to have arisen from the Federal Power Commission, on the grounds that the Compact violates the long-established policy of the Federal Government regarding the development of hydro-electric energy, and that the Attorney-General of the United States has taken the position that the Compact was defective in that it did not provide for the transfer of title to the Federal Government of all lands and easements purchased by the States for flood-control purposes.

---

[69] *Public Resolution No. 36*, 72d Cong.; and Senate Joint Resolution 148.

[70] *Public Resolution No. 94*, 75th Cong., 3rd Session; also House Joint Resolution No. 150.

The position of the Federal Power Commission has been expressed[71] by its general counsel, Oswald Ryan, who states that the Commission's position can be properly evaluated only when examined in the light of the legal questions which the Compacts have raised. In this connection, Mr. Ryan states that the purpose of his paper[71] "is to discuss not the questions of policy, but the questions of law which must inevitably be faced in considering not only the Connecticut and Merrimac Compacts, but all other flood control compacts which may hereafter be proposed in connection with the program of flood control, authorized by the Flood Control Act of 1936." The position of the attorney for the Federal Power Commission has been resisted strenuously by the Governors and Attorney-Generals of the compacting States.

Compact Covering the Waters of the Delaware River Between the States of New York, Pennsylvania, and New Jersey.—Interstate Compacts between the States of New York, Pennsylvania, and New Jersey were negotiated in 1925 and 1927, but these Compacts were ratified only by the Legislature of the State of New York. The failure of ratification resulted in the litigation between New Jersey and New York (in which the State of Pennsylvania intervened for the protection of its equities in that stream), in the Supreme Court of the United States, which action is discussed herein under "Interstate Litigation."

Interstate Negotiations Concerning Pollution of the Delaware River.—The States of Delaware, New Jersey, New York, and Pennsylvania have heretofore created an Interstate Commission for the consideration of the control of pollution of the waters of the Delaware River. Similar conferences have been conducted by representatives of the States of New York, Pennsylvania, West Virginia, Ohio, Kentucky, Indiana, Illinois, and Tennessee, looking to the consummation of a compact for the control of pollution of the Ohio River.

Compact for Potomac River.—Pursuant to Public Resolution 74, Seventy-fifth Congress, the States of Pennsylvania, Maryland, Virginia, and West Virginia, and the District of Columbia are authorized to enter into a compact for the abatement of the pollution of the Potomac River. For this purpose, the four States and the District of Columbia have organized the Potomac Valley Pollution Conference, the purpose being to draft a compact to cover the problems involved.

Compact Between the States of Ohio and Pennsylvania Concerning the Waters of Pymatuning Lake.—This Compact relates to the development, use, and regulation of Pymatuning Lake, and the State-owned land surrounding it, for fishing, hunting, recreational, and park purposes. It was ratified by the Legislature of Ohio on May 18, 1937; by Pennsylvania on June 5, 1937; and approved by the Congress of the United States on August 28, 1937.

Compact Between the States of New York, New Jersey, and Connecticut Concerning Abatement of Pollution of Coastal and Tidal Waters.—On August 27, 1935, the Congress approved a Compact between the States of New York, New Jersey, and Connecticut, covering control and abatement of pollution in the harbor, coastal, and tidal waters of these States.

---

[71] *Public Utilities Fortnightly*, January 20, 1938.

Negotiations for Compact Between Colorado, Wyoming, and Nebraska, Covering the Waters of the North Platte River.—Negotiations between representatives of these three States, looking to a compact on the North Platte River, which rises in Colorado and flows thence into Wyoming and Nebraska, have been conducted for many years. It is probable that the States of Colorado and Wyoming could have reached an agreement concerning their relative equities in the waters of this stream, in so far as such uses in the North Platte Basin in Colorado and a nominal trans-mountain diversion of water out of the North Platte River into the Basin of the South Platte River in Colorado were concerned. Colorado, however, insisted upon a larger trans-mountain diversion out of the North Platte Basin than Wyoming would concede. As a result, negotiations between the two States were ended abruptly on December 4, 1933. Since that time little attempt has been made to reach an understanding.

Throughout these negotiations, Nebraska took the position that it could not negotiate a compact which might adversely affect uses of water in that State. As a result of failure to reach an agreement, Nebraska filed its original bill of complaint against the State of Wyoming in December, 1935, in which Colorado was later made an impleaded defendant (see heading "Interstate Litigation"[17]).

Negotiations Between Colorado and Nebraska, Covering the Waters of the North and South Forks of the Republican and the Arikaree Rivers.—Negotiations between Commissioners representing the States of Colorado and Nebraska have been conducted intermittently since 1934, with a view to a compact covering the waters of the aforementioned streams, which head in Colorado and flow into Nebraska. It appeared at one time that an agreement would be reached; but, upon advice of the Attorney-General of Nebraska that the Commissioner for that State could not enter into a compact, the terms of which would invalidate or limit any decreed, existing, appropriation of water in Nebraska, that State declined to continue the negotiations, and nothing further has been accomplished. Nebraska also took the position that the State of Kansas (through the northeast corner of which the South Fork of the Republican River flows) was a necessary party to any interstate agreement. The Commissioner for Kansas advised that he was agreeable to participating in negotiations, but, due to the afore-assigned reasons, the negotiations were allowed to lapse. It is thought that the decision of the Supreme Court, in the case of Hinderlider *vs.* La Plata River and Cherry Creek Ditch Company,[28] which recognizes the authority of States to negotiate interstate compacts irrespective of their effect upon private vested rights, removes any valid objection heretofore raised by Nebraska in this connection.

Negotiations Between Colorado and Wyoming Concerning the Waters of the Little Snake River.—Authorization has been given the State Engineers of Colorado and Wyoming to enter into negotiations concerning the division of the waters of the Little Snake River, which is an interstate stream common to Colorado and Wyoming. This stream which rises in Colorado crosses the Wyoming-Colorado State line four times. Considerable irrigation development has occurred along this stream, and decrees and permits have been issued for the use of water in both States. Ditches decreed in Colorado irrigate lands both in Colorado and Wyoming, whereas ditches decreed in Wyoming likewise irrigate lands in both States. As a result of this condition, rather important questions of administration have arisen between the administrative officials of the two States. The laws of Colorado and Wyoming prohibit the diversion of water arising in either State, for use in another State, which makes the administration of these interstate ditches a subject of interstate dispute. Thus far (1939), however, no active negotiations for a compact have been entered into. Field surveys and studies of land and water resources in the two States needful for a full understanding of the needs of both States are now being made by the U. S. Bureau of Reclamation. Further negotiations for a compact suspended pending results of investigations by the Bureau.

Negotiations for an Interstate Compact Between Colorado, New Mexico, Utah, and Wyoming, Covering the Waters of the Colorado River.—Soon after the approval of the Boulder Canyon Project Act by the Congress, a conference of the representatives of the four upper States of the Colorado River Basin was convened to consider the desirability of a four-State compact to divide between these States the 7 500 000 acre-ft of water allocated to the upper basin States by the compact. This conference disclosed that the representatives of Colorado, New Mexico, and Wyoming were ready to proceed with negotiations looking to a four-State compact. Utah, however, declined to undertake negotiations pending the completion of the comprehensive survey and study of the land resources of the four upper-basin States of the Colorado River Basin, which the Secretary of the Interior, under the provisions of the Boulder Canyon Project Act, was directed to make. These investigations have been in progress since 1929, but will not be completed until possibly 1942.

Further negotiations for a four-State compact are not contemplated at this time (1939).

MEMOIRS OF DECEASED MEMBERS

HARRISON PRESCOTT EDDY, Past-President, Am. Soc. C. E.[1]

DIED JUNE 15, 1937

Harrison Prescott Eddy was born in Millbury, Mass., on April 29, 1870, the son of William Justus and Martha Augusta (Prescott) Eddy. He was a descendant of John Eddy, born in March, 1597, in Boxted, Suffolk County, England, who came to Plymouth, Mass., in 1630.

Mr. Eddy obtained his early education in the public schools of Worcester, Mass. In 1891 he was graduated from the Worcester Polytechnic Institute with the degree of Bachelor of Science in Chemistry.

Finding immediate employment in the Sewer Department of the City of Worcester, Mr. Eddy served for one year in charge of the disposal works, and, thereafter, for fifteen years as Superintendent of the Department. During this period he constructed by day labor approximately one hundred miles of sewers and drains, enlarged the chemical treatment plant, installed sludge-drying equipment, and added forty-three acres of intermittent sand filters to the disposal system. As Superintendent, he also had charge of all departmental activities, including the investigation of sewage treatment processes and of stream pollution, in which he was fortunate in a stimulating association with the late Leonard P. Kinnicutt, an internationally recognized authority in sanitary chemistry. Thus, coincidentally with the classic experiments in sewage treatment of the Massachusetts State Board of Health at Lawrence, Mass., Mr. Eddy obtained in the operation of the Worcester plant an unusually valuable experience in the early development in the United States of the art of sewage disposal.

In 1906, as a result of his work in Worcester, Mr. Eddy was recommended by the late Samuel M. Gray, M. Am. Soc. C. E., as a member of a board of engineers to develop a new system of sewers for Louisville, Ky. This was Mr. Eddy's first engagement as a Consulting Engineer on an important project.

In 1907, he formed a partnership with the late Leonard Metcalf, M. Am. Soc. C. E., under the firm name of Metcalf and Eddy, which continued until the death of Mr. Metcalf early in 1926, when a new partnership which included a number of previously associated partners and assistant engineers was formed under the original name. The association of Harrison Eddy and Leonard Metcalf was most fortunate. Both foresaw an opportunity for a broad-scale, liberally planned practice; both recognized an obligation to do their parts in the advancement of their chosen profession by active participation in the work of various technical societies. Since its organization the firm of Metcalf and Eddy has been accorded a foremost place in its field of work.

---

[1] Memoir prepared by Frank A. Barbour and J. H. Kimball, Members, Am. Soc. C. E.

During his thirty-one years of practice as a Consultant, Mr. Eddy rendered service to more than 125 cities and towns in problems of water supply, water purification, sewerage, sewage disposal, industrial waste treatment, and municipal refuse disposal. Reference can here be made only to a few of these engagements.

In 1906, he prepared the general plan for the improved sewerage of Louisville; in 1910, he designed and supervised the construction of one of the earlier Imhoff tank-trickling filter plants at Fitchburg, Mass.; in 1911, he investigated for the Metropolitan Sewerage Board of New York City the effect of the discharge of sewage into local waters; in 1912, he reported to the City of Cincinnati, Ohio, on the pollution of the Ohio River in relation to its use for water supply. He prepared general plans of sewerage and detailed plans of sewage treatment plants for Akron and Dayton, Ohio, and for Allentown, Pa. In 1918, he investigated and reported to the City of Cleveland, Ohio, on sewage disposal. As a member of a Board of Engineers he participated in 1920 in a general plan for interception and sewage treatment at Milwaukee, Wis.; in 1924, he was a member of the Chicago Engineering Board of Review appointed to investigate and report on the lake lowering controversy, including a study of water supply and purification for the City of Chicago, Ill.; in 1925, he was a member of the Board which developed for the City of Detroit, Mich., a general plan of sewerage interception and sewage treatment; from 1926 to 1928, he was a member of a Board which reported on additional water supply for the City of New York; from 1934 to 1936, he participated in the investigation of sewage disposal for the District of Columbia and prepared construction plans for the treatment works recommended; in 1935, for the Metropolitan District of Southern California, he investigated the problem of softening the Colorado River supply and made general plans of the plant recommended.

Among the other municipalities to which Mr. Eddy rendered service were included: New Orleans, La.; Pittsburgh, Pa.; San Francisco, Calif.; Portland, Ore.; San Antonio, Tex.; Boston, Mass.; and Toronto, Ont., Canada. He was a member of the Technical Board of Review appointed by the Federal Public Works Administration in 1935 to pass upon public works projects, also of a Board of Consulting Engineers appointed in 1936 by the Tennessee Valley Authority to advise in problems of flood relief in the Tennessee River Valley. At the time of his death, Mr. Eddy was serving as one of the Consulting Engineers to the New York Board of Water Supply on the Delaware River project and also as a Consultant to the Water Resources Service of the Department of Forests and Waters of the State of Pennsylvania, relative to the water supply of Pittsburgh, Harrisburg, and Philadelphia, Pa. Briefly summarized, Mr. Eddy's engagements may be said to have involved participation in a large proportion of the major water supply and sewerage problems which have required investigation during the three decades of his private practice.

It is significant that although he was trained as a chemist—a line of study that was largely theoretical—he turned his attention shortly to the very practical details of supervising a large amount of construction. To this combination those who knew him well attributed his keen capacity for solving technical problems having various difficult phases, while at the same time keeping a very sound view of the practical features involved. His early experience as an executive in the management of a city department was reflected in the promptness and dispatch with which he disposed of matters before him.

As a speaker, Mr. Eddy was convincing; and his unusual gift for simple, logical presentation of his thoughts made him a valuable witness in numerous important litigations, among which may be mentioned the inter-State cases of New York *vs.* New Jersey, relative to the proposed discharge of Passaic Valley sewage into New York Harbor; Wisconsin *vs.* Illinois and the Sanitary District of Chicago; New Jersey *vs.* New York relative to the taking of the Delaware River for additional water supply for the City of New York; Connecticut *vs.* Massachusetts relative to the taking of water from the Ware and Swift Rivers for the additional supply to the Boston Metropolitan District.

Mr. Eddy contributed numerous valuable papers to various technical organizations. He was joint author of the generally accepted, standard, three-volume treatise on "American Sewerage Practice," and of the textbook entitled "Sewerage and Sewage Disposal." In 1920, the Boston Society of Civil Engineers awarded him the Desmond Fitzgerald Medal for his paper[2] on "Maximum Rates of Precipitation at Boston for Various Frequencies of Occurrence." In 1925 he was awarded the Norman Medal of the American Society of Civil Engineers, for his paper[3] on "Imhoff Tanks—Reasons for Differences in Behavior"; and in 1927, the Rudolph Hering Medal was given to him by the Sanitary Engineering Division of the Society for this same paper. All his published material is characterized by careful, time-consuming development of the controlling facts.

He was a member of numerous technical organizations, including the American Institute of Consulting Engineers, the Institution of Civil Engineers of Great Britain, the Institution of Sanitary Engineers of Great Britain, the Engineering Institute of Canada, the American Society for Testing Materials, the Boston Society of Civil Engineers, the American Water Works Association, the New England Water Works Association, the American Public Health Association, the American Society for Municipal Improvements, and the American Chemical Society. His attainments were recognized by many of these organizations by election to office and honorary membership.

In 1914 he was made President of the Boston Society of Civil Engineers, and in 1925–1926, Vice-President of the American Institute of Consulting Engineers. Mr. Eddy was awarded Honorary Membership by the Boston Society of Civil Engineers, New England Water Works Association, and the Institution of Sanitary Engineers of Great Britain. His last journey to Montreal was made to receive Honorary Membership in the Engineering Institute of Canada, but his death intervened in the early morning of June 15, 1937, only a few hours before the award was scheduled to take place. In 1930 he was made Doctor of Engineering by the Worcester Polytechnic

[2] *Journal*, Boston Soc. of Civ. Engrs., Vol. VII (1920), p. 47.
[3] *Transactions*, Am. Soc. C. E., Vol. 88 (1925), p. 465.

Institute, and, in 1931, Northeastern University of Boston awarded him the same degree.

Throughout his professional career, Mr. Eddy was deeply interested in the Society and in its Sanitary Engineering Division; but it was not until 1927, when he was officially nominated for Director from District No. 2, that he was brought prominently into the work of the organization as a whole. From then on until his death, he was continuously in this service, either as an officer, as an official representative, or as a member of some important committee.

During his term as Director (1928–1930), he made a deep impression on his associates by his ability and conscientious service. This was recognized in the fall of 1933 when he was enthusiastically nominated for the office of President. His work as President, and during the following two years as Past-President was of great value to the Board and the Society. Many important committees felt the impress of his judgment, among which may be mentioned the Technical Procedure Committee, the Committee on Public Works, and especially the Executive and the Publications Committees. From its inception he was deeply interested in the ideals and progress of the Engineers Council for Professional Development, to which he gave generously of his time and thought, as with all other of his professional duties.

It was during the depth of the economic depression that Mr. Eddy served as President of the Society. This was hardly a time in which a spectacular showing could be made but it was a period of very strenuous personal work. Important committees, such as those on Hydraulic Research, and on Flood Protection Data, were appointed; practice was established for the defense of Society members unjustly accused; the relations of Federal relief agencies to engineers were investigated; a code of fair practice for the Engineering Division of the Construction Industry was studied intensively; and a liberal policy was instituted in favor of those members who had suffered severe financial loss in the depression. All this work for the Society demanded a great sacrifice of time and effort, which Mr. Eddy cheerfully gave. He even assigned one of his own office staff to assist him in his studies of Society duties and opportunities. Many trips to New York and Washington were required. He estimated that during the first six months of his incumbency he visited Washington, in the interest of the Engineering Profession, at the rate of one day a week for the twenty-six weeks.

In May, 1932, between his terms as Director and President, he was appointed on the Society's Committee on Public Works, which entailed extensive activity including many interviews in Washington with Congressional leaders and others. Through this Committee, the Society was enabled to share generously in efforts for the enactment of the Emergency and Relief Act of 1933 whereby, under the Public Works Administration, many engineering projects were constructed. His influence with the administrators of Title II of this Act was great and many of its features had his close attention. The passage of this Act resulted in the employment of thousands of engineers at a time when there was a great hardship among members of the profession due to unemployment.

One of Mr. Eddy's great services came during his term as Director (1928–1930) when he served continuously on the Committee on Publications, being Chairman in 1930. This Committee had to consider the vital question of the feasibility and propriety of establishing an illustrated Society monthly. In April, 1930, the Committee made a report to the Board of Direction, suggesting the publication of "a journal under the title *CIVIL ENGINEERING* to contain those papers of a more popular character, items relating to Society activities, and other material of general appeal to the membership." It is typical of Mr. Eddy that his decision on this matter was made only after many conferences with officers and staff and a careful study of the functions and possibilities of the project. After the decision to undertake the new publication was reached, he gave unstintedly of his time in helping to develop the character of *Civil Engineering*.

At the time of his death Mr. Eddy was generally recognized as the Dean of American Sanitary Engineers. His success was due to an unlimited capacity for work, to power of concentration, to a mental discipline—which enabled him in the later years of his life to triumph over serious physical disability, and to a character and intellect which engendered an enduring confidence in his opinion and advice. Dignified but possessed of a keen sense of humor, he was a delightful companion and a firm friend. He was a considerate employer, and his helpful interest in the work of young engineers was notable.

It is not too much to say that Mr. Eddy was outstanding in every human and professional relationship. His status in the minds of his fellow engineers was thus epitomized in the July, 1937, *Civil Engineering:* "His character was noble, his counsel wise, his friendships true. Few engineers will leave as deep an impression on their generation as Harrison P. Eddy."

He was married on June 1, 1892, to Minnie Locke Jones, of Worcester, who, with three children, Harrison Prescott, Randolph Locke, and Mrs. Charles W. Eaton, survives him.

Mr. Eddy was elected an Associate Member of the American Society of Civil Engineers on May 7, 1902, and a Member on January 3, 1907. He served as a Director of the Society from 1928 to 1930 and as President in 1934.

ALGERNON BROWN ALDERSON, M. Am. Soc. C. E.[1]

DIED MAY 13, 1939

Algernon Brown Alderson, the son of Thomas Brown and Eleanor (Sutton) Alderson, was born in London, England, on November 6, 1867. He was educated in the Taplow Grammar School near London, the Bristol Grammar School and Cliftonville College at Brighton, England. After coming to America he studied in the Ottawa Collegiate Institute at Ottawa, Ont., Canada, and decided on civil engineering as his life work.

---

[1] Memoir prepared by F. B. Chamberlin, Esq., Town Engineer, West Hartford, Conn.

In his early career, from 1887 to 1897, Mr. Alderson served in the following positions: Chainman and Rodman with the Pennsylvania, Slatington and New England Railroad Company; Draftsman for the Pennsylvania Railroad Company; Draftsman for the Inter-Continental Railway Commission, Ecuador and Peru; Draftsman and Assistant Engineer for the Baltimore Traction Company; Draftsman for the New York, New Haven and Hartford Railroad Company; Draftsman and Assistant Engineer on design and construction of sanitary sewers for Bristol, Conn.; private practice in Bristol; and Assistant Engineer in charge of surveys for additional water supply for the City of New Britain, Conn.

In 1898 Mr. Alderson moved to West Hartford, Conn., where he engaged in private practice and at the same time acted as Engineer for the town whenever his services in that capacity were required. When the town set up an engineering department in 1915 he became the first Town Engineer and served in that capacity until 1918. During these twenty years with the Town of West Hartford he saw it grow from a small farming community of a few thousand to a sizable residential suburb; and, in connection with this growth he contributed much in the design and construction of several sanitary sewerage systems, improved pavements, sidewalks, drainage systems, and various other improvements required by such expansion.

From 1918 until his death Mr. Alderson was engaged in private practice as an Engineer and Surveyor with the exception of short periods when he was employed by the Town of West Hartford and by the Connecticut State Highway Department.

He was born to the engineering profession as his father was a member of the Institute of Mining Engineers of England and had extensive experience in the management of properties in Spain, Norway, and his native country. A brother in England is also a civil engineer and served as a Major in the Royal Engineering Corps during the World War.

Mr. Alderson was a life member of the Connecticut Society of Civil Engineers and a member of Wyllys Lodge, A. F. and A. M., of West Hartford. He was always a highly respected citizen of the community and gave considerably more than his professional services toward the welfare of the town.

On October 26, 1897, he was married to Anne Geneva Gladden of New Britain. He is survived by his widow and two daughters, Mrs. Ralph L. Dame and Mrs. Alderson Magee.

Mr. Alderson was elected an Associate Member of the American Society of Civil Engineers on October 2, 1907, and a Member on October 29, 1912.

WALTER HINDS ALLEN, M. Am. Soc. C. E.[1]

Died April 19, 1938

Walter Hinds Allen was born in Newton Highlands, Mass., on January 9, 1875. His father, Walter Allen, was born in Worcester, Mass., and his mother, Grace Mason (Weston) Allen, was born in New Braintree, Mass. Both parents came of Massachusetts Colonial stock. His father's first American ancestor settled in the vicinity of Boston, Mass., in 1640. His mother was of direct *Mayflower* descent. Successive generations were reared in the New England atmosphere and tradition.

---

[1] Memoir prepared by Captain Ralph Whitman (CEC), U. S. Navy, M. Am. Soc. C. E.

Walter Hinds Allen received his elementary education in the Public Schools of Newton Highlands and, later, attended High School in New Haven, Conn., from which he was graduated in 1891. He then entered Yale University, at New Haven, Conn., and was graduated with the degree of Bachelor of Arts in 1895. This education was supplemented by a course as Larned Scholar in the Yale Graduate School from 1895 to 1898, during which period (in 1896) he received the degree of Bachelor of Philosophy from the Sheffield Scientific School. During this period also, he was employed at times as a member of the Instructing Staff in engineering subjects.

The outbreak of the Spanish-American War occurred toward the end of his college courses. Mr. Allen had been for some time a member of the Connecticut Naval Militia. In June, 1898, he enlisted in the United States Volunteer Navy, being given initially the rating of seaman. His qualifications and natural ability obviously indicated employment in a different capacity, but the standard procedure of the Navy provided no regular means for this unusual case and the natural preoccupation of the naval authorities with the conduct of the War made an alteration in his status irregular and somewhat difficult. His lack of sea training barred him from a commission in the line of the Navy, and legal obstacles prevented his appointment as a midshipman or naval cadet, titles which were reserved for young men appointed to the Naval Academy in regular course. However, a way was found. He was appointed an Acting Naval Cadet, a matter in which he always took much pride. The writer has heard him refer to it as the only case of its kind.

Being honorably discharged from the Navy in September, 1898, Mr. Allen began his active civil engineering career as Rodman in the service of the New York, New Haven and Hartford Railroad Company, going shortly afterward to the Mexican International Railway Company as Transitman. In quick succession he moved to the position of Leveler and Topographer with the Kansas City, Mexico and Orient Railway Company and back to the New York, New Haven and Hartford Railroad Company as Transitman and Assistant Division Engineer.

Leaving railroad work in 1903, he was commissioned in June of that year as Civil Engineer, United States Navy, with the rank of Lieutenant, Junior Grade. He was advanced to the rank of Lieutenant in 1906, and to that of Lieutenant-Commander in 1914. Incident to the expansion of the commissioned naval personnel in the World War, he was commissioned as Commander (temporary), Civil Engineer Corps, U. S. Navy, in July, 1918. This commission was made permanent in 1921. In 1924, he attained the rank of Captain in the Civil Engineer Corps, and retained this rank until the time of his death.

Captain Allen's duties in the Civil Engineer Corps of the Navy took him to many stations. Successively, he served at the Navy Yards at New York,

N. Y., and at Charleston, S. C.; at the Naval Ammunition Depot, Hingham, Mass.; Bureau of Yards and Docks, Navy Department, Washington, D. C.; again, at the Navy Yard, New York; then at the U. S. Naval Station, Olongapo, Philippine Islands; a third time at the New York Navy Yard; then at the U. S. Naval Training Station, Great Lakes, Ill.; Navy Yard, Philadelphia, Pa.; Navy Yard, Puget Sound (Bremerton), Wash.; U. S. Naval Operating Base, Hampton Roads (Norfolk), Va.; a second time at the Bureau of Yards and Docks; and, lastly, at Headquarters, 12th Naval District, San Francisco, Calif. In each of these field duties, except his first upon induction into the Naval Service, he was Senior Officer of his Corps at his station.

In so diversified a career, and with the variety of duties entailed, a list of projects with which Captain Allen was connected cannot be recorded in a memoir of reasonable length. Mention may be made of the large dry dock at Charleston built under his supervision when he was only thirty-one years old. In his last duty in Washington, he served four years (1930–1934) as Design Manager of the Bureau of Yards and Docks in charge of design of the Navy's shore station structures involving many millions of dollars.

It is characteristic of Captain Allen that in later years his conversation turned frequently upon his World War service at the U. S. Naval Training Station, Great Lakes, and not so much upon the technical aspects of it as upon the human relations involved. In addition to supervising the great quantity of war construction necessary for this station—one of the nation's largest training stations—he took a leading part in organizing and directing the activities of the Twelfth Regiment, the "Public Works Regiment" composed of raw recruits sent to the Station for initial training for Naval Service. In this regiment, they were trained for the design, construction, and maintenance of shore station activities in continental United States and abroad. From it, more than 18 000 men were sent to the Atlantic seaboard, to the Fleet, and to Europe. Among those who went to Europe were the Railroad Force to assemble and operate the locomotives and cars for the 14-in. railroad guns on the Argonne front. These were naval guns adapted for the new purpose. The ésprit of this body of young men, from many parts of the country, and with a vast diversity of origin and personal background, became notable even in the short time they were together. It is significant that upon Captain Allen's separation from this organization he was presented with the "regimental colors," a handsome flag about 4 ft hoist by 6 ft fly, of heavy silk richly embroidered and with gold fringe. This flag was one of his prized possessions. He had it with him wherever he went, and it was displayed in the interment services at the National Cemetery at Arlington, Va. These services were conducted with full military honors on May 3, 1938, following more intimate services at his residence in San Francisco, Calif., on April 21.

The same qualities that emphasized his relations with his regiment at the Great Lakes Station manifested themselves later in his activities with and in behalf of the Civil Engineer Corps of the United States Naval Reserve. In 1935, while he was on duty in the Navy Department as War Plans Officer of the Bureau of Yards and Docks, his personal efforts stimulated interest in this important branch of national defense among young engineers throughout the country. Upon being transferred to San Francisco in the fall of 1936 Captain Allen carried with him the same infectious enthusiasm. This trait is well described by Commander Frank M. Harris, U. S. Naval Reserve, who has written of Captain Allen that: "He possessed the peculiar ability to attach young men to himself and to encourage them to give their best efforts to any cause in which he was leading them." In such way he had impressed himself upon the community of a large city in only a year and a half of residence following his arrival there as a stranger.

The writer has preferred to dwell upon human attributes more than on professional qualities and attainments, and to write of the man rather than of his work. The work was shared by others. His nature was exclusively his own. Pre-eminently it was Captain Allen's social instincts that endeared him to those who knew him. He was essentially social and companionable, pleasantly aggressive in his loyalty to those with whom he was associated, whether superiors or sub-ordinates, and very lovable. Combining balance with youthful enthusiasm and sympathy, at sixty-three he was still a young man. This nature left its imprint upon all who became associated with him in any way, and increasingly with the length of the association.

Captain Allen was a member of the Society of American Military Engineers, and a Companion of the Military Order of the Loyal Legion. He also belonged to the Graduates Club, in New Haven; the Army and Navy Club, of Washington, D. C.; the Army-Navy Country Club (Washington); the Mountain View Country Club, Greensboro, Vt.; and during his residence in the respective localities had belonged to the Yale Clubs of Boston, Mass., Washington, D. C., Chicago, Ill., Philadelphia, Pa., Seattle, Wash.; and also to the Presidio Golf Club and the Engineers Club of San Francisco.

In January, 1906, he was married to Edith Stark Hancock, who, with a daughter, Edith Isadora Allen, survives him. He is also survived by a brother, the Hon. J. Weston Allen; and by three sisters, Mrs. F. S. Hollis, Mrs. J. N. Eaton, and Mrs. Alice A. Bonham.

Captain Allen was elected a Junior of the American Society of Civil Engineers on May 1, 1900; an Associate Member on November 4, 1903; and a Member on February 4, 1908.

JOSEPH CHESTER ALLISON, M. Am. Soc. C. E.[1]

DIED MAY 29, 1936

With the passing of Joseph Chester Allison, the Southwest lost not only a brilliant engineer, but also a successful colonizer and financier. It is not usual to find such a combination of talent in civil engineers who are prone to limit their activities and thought along strictly professional lines. In the case of Mr. Allison, even the absence of a complete college training was no obstacle to a successful engineering career and the consummation of large enterprises.

---

[1] Memoir prepared by A. L. Sonderegger and Ray S. Carberry, Members Am. Soc. C. E., and H. M. Rouse, Assoc. M. Am. Soc. C. E.

Born in San Diego, Calif., on July 12, 1884, young Allison attended the Grammar School and the first few years of High School in his native city. He was graduated from the Los Angeles (Calif.) High School in 1901, and was enrolled for the engineering course in Stanford University, at Stanford University, Calif. Ill health, however, forced him to stop university training and to take up outdoor work as an aid physically. Thus, he went to work in 1902 with the California Development Company in Calexico, Calif., as a helper on a surveying crew. This Company at that time was promoting the reclamation of the desert of Imperial Valley by the diversion of the Colorado River water, near Yuma, Ariz. Mr. Allison soon advanced to the position of Assistant Engineer under the leadership of Mr. C. R. Rockwood, and the late C. N. Perry, H. T. Cory, and F. C. Herrmann, Members, Am. Soc. C. E., all of whom successively occupied the position of Chief Engineer. It was Mr. Allison's privilege to be entrusted with a position of responsibility during the break of the Colorado River in 1906–1907, which threatened the permanent inundation of Imperial Valley. Subsequently, when the Company was confronted with the problem of reconstructing the canal structures which had been installed during the first years of the Imperial Valley enterprise and, of necessity, were of more or less temporary type, Mr. Allison proved himself to be an adept superintendent of construction. Climatic, geological, and physiographical conditions in the Imperial Valley, which confront the engineer, are unusual and demand an instinctively clear conception of the natural phenomena indigenous to that country. Mr. Allison, who ate and slept on the job for years, began to know the River and the soil.

The disastrous events of 1905, 1906, and 1907 finally forced the California Development Company into receivership, in January 1910. The receiver, William H. Holabird, soon recognized young Allison's ability and promoted him to the position of Chief Engineer; and in 1912 he became Chief Engineer and Assistant General Manager, which position he held until the termination of the receivership, in 1916.

Mr. Allison's first major undertaking was the reconstruction of Sharp's Heading, in Mexican territory, which is still the main point of diversion for the lateral canal system of Imperial Valley. In the meantime, the irrigation enterprise was expanding rapidly, and in 1911 the northern part of Imperial Valley was organized into Imperial Water Company No. 3. Mr. Allison, as Consulting Engineer for this water company, designed and supervised the construction of its canal system which, laid out along new lines, proved eminently satisfactory.

As Consulting Engineer for the Receiver, from 1912 to 1915, one of the writers had an opportunity to know Mr. Allison and his capacity as an organizer, construction engineer, and executive. He was particularly impressed with the resourcefulness of the young engineer and his exceptional understanding of the problems presented by the Colorado River and the delta formation which baffled more than one engineer. Thus, Mr. Allison's early training and the long fight with the River served, successfully, in later years, to meet the problems that continually confronted his Company, not only at the Colorado River Heading, but also at every point where structures and local conditions required the solution of questions of unusual character.

There was one dual problem which presented itself year after year: First, around the Fourth of July, the threatened invasion of the flood waters of the Colorado River along the levees of the Alamo Canal and Volcano Lake; and second, about two months later, a threatening water famine due to the combination of a low-water stage of the River with a river-bed which previous floods had scoured away below the sill of the Alamo Canal Intake at Hanlon, on the west bank of the river below Yuma. Year after year, these baffling conditions were met successfully. During a year of extremely low run-off (1913), Mr. Allison succeeded in building a diversion weir across the River, by the hydraulic process.

However, the spirit of the pioneer asserted itself also along commercial lines. While he was Chief Engineer of the California Development Company, Mr. Allison, in co-operation with Mr. Sydney McHarg, his brother-in-law, and others, became identified with the organization of the First National Bank in Calexico, with a branch office in Mexicali, on the Mexican side of the international boundary line. Mr. Allison became a Director, in 1912.

In 1916, when the assets of the California Development Company were acquired by the Imperial Irrigation District, Mr. Allison entered the field of private practice in Calexico and shortly thereafter became associated with the late Paul M. Entenman, Assoc. M. Am. Soc. C. E. Mr. Allison acted in consulting capacity for the Imperial Irrigation District, Imperial Mutual Water Companies, Imperial Valley Cities, Palo Verde Mutual Water Company, etc.

The opportunity presented itself in those years for colonization on the Mexican side of the Colorado River Delta. Mr. Allison and his associates saw possibilities in land development on a large scale in the delta lands of the Colorado River in Baja California, Mexico. The first enterprise undertaken in partnership with Messrs. Sydney McHarg and Tom Daley was the Alamo Mocho Plantation Company, which included the improvement of a large tract of virgin land. Irrigation water was supplied from the Alamo Canal of the Imperial Irrigation District, which enters Mexico a short distance below the point of diversion. The land was planted to cotton, under individual tenancy of small tracts by Mexicans and Chinese. Mr. Allison was the guiding spirit of the engineering features, as well as of the financial and commercial aspects. This project was completed successfully.

Mr. Allison then organized the Delta Land Company and leased 102 000 acres of virgin delta land from the Colorado River Land Company. He also organized the Delta Canal Company. This latter company installed its own irrigation systems and the cropping was subleased to Mexican, Japanese, and Chinese ranchers. These lands were developed by two processes: One by means of a large pumping plant on the Alamo Canal, together with three large deep wells; and the other by a large gravity diversion from the Alamo Canal. Later the Alamo Canal gravity diversion was augmented by a direct diversion from the Colorado River by the installation of siphons on an exceptionally large scale. This second enterprise also proved highly successful, Mr. Allison brilliantly justifying his reputation as an engineer, promotor, and financier.

In the well-known controversy about the All-American Canal Project of Imperial Valley, Mr. Allison used his pen as well as his personal influence in favor of the Mexican route, as he was doubtful of the success of the project, both from a technical and financial point of view.

In 1924, he opened offices in Los Angeles, Calif., and established his residence in La Jolla, San Diego County, in 1925.

Cotton being the principal crop of the plantations in Baja California, Mr. Allison conceived the project of warehousing the crop at the port of San Diego instead of Los Angeles. To this end, he incorporated, in 1928, the San Diego Municipal Warehousing Corporation. The authorities of the City of San Diego lent their assistance to this venture by giving the Company a lease on 9½ acres of tideland. A spacious warehouse was built and the operation of a general warehousing business initiated. This business was successful through the years of the depression. In order to further shipping through the Port of San Diego, Mr. Allison undertook a trip to Mexico, and Central America in 1935, establishing promising business connections.

Mr. Allison died suddenly on May 29, 1936.

Mr. Allison was first married to Gladys Mitchell, who bore him two children; she died in 1921. In 1922 he was married to Carlotta Snow, who, with his five children, survives him. Always a loving and devoted husband, and greatly attached to his children, his memory will be held very dear to those he left.

The passing on, in the prime of life, of a man like Joseph Chester Allison is always a great loss to his country. A man of exceptional ability, he combined the qualities of an engineer with the sound judgment and foresight that make the successful business man.

Mr. Allison was elected an Associate Member of the American Society of Civil Engineers on September 3, 1912, and a Member on June 12, 1917.

EDWIN PERCIVAL ARNESON, M. Am. Soc. C. E.[1]

Died December 7, 1938

Edwin Percival Arneson was born in Fort Worth, Tex., on July 25, 1888, the son of A. and Emma (Grimland) Arneson. His grandparents were truly pioneers in Texas in a day when it took character and tenacity to settle and make a living in that State. His maternal grandfather arrived in Texas in 1848 and the paternal grandfather in 1868, both coming to the New World from Norway. Edwin attended the public schools of Fort Worth and the Agricultural and Mechanical College of Texas at College Station, Tex. He received the degree of Bachelor of Science in Civil Engineering in 1910, and the degree of Civil Engineer in 1929, from the latter school.

---

[1] Memoir prepared by a Committee consisting of E. W. Robinson, and A. P. Rollins, Members, Am. Soc. C. E., and P. S. Park, Esq., and Harry P. Drought, Esq., both of San Antonio, Tex.

His first position after leaving college was with the Texas Company at Houston, Tex., on the design of warehouses, wharves, and similar structures. From 1911 to 1913 he was engaged as Office Engineer for the Medina Irrigation Company of San Antonio, Tex., on the canal system in connection with Medina Dam project. From 1913 until the work was stopped by the outbreak of the World War in 1914 Mr. Arneson was Resident Engineer on various large projects in Spain for the Ebro Irrigation and Power Company of Barcelona.

From 1914 to 1915 he was in immediate charge of surveys and studies for a drainage project at Waco, Tex., and from 1915 to 1916 was Chief Draftsman in the office of the City Engineer of San Antonio, supervising the design of extensive municipal improvements. From December, 1916, to March, 1930, with the exception of a brief period in Washington, D. C., he was a member of the firm of Walton and Arneson, Civil Engineers of San Antonio, and engaged in topographic surveying, irrigation, highway projects, and structural work. During the World War he served in the Navy Department in Washington in the capacity of Structural Draftsman on the design of ship-building ways, crane runways, and water-front improvements.

From March, 1930, until his death, Mr. Arneson maintained his own office in San Antonio for the general practice of Civil Engineering. Besides the usual run of general practice, he was frequently called into consultation on, and engaged to do, highway location by the Texas State Highway Commission. Because of the fine reputation he had acquired as a locating engineer he was employed by several of the more populous counties of Texas to prepare a master-highway plan for the larger cities in those counties, and it was in this line of work that he became recognized as an outstanding engineer. Dallas, Fort Worth, Waco, San Antonio, and Corpus Christi, Tex., have master plans designed by him. Nueces Valley Authorities' Flood Control and Irrigation Enterprise, and the San Antonio River Beautification Project (his last work) bear further testimony to his engineering skill and vision. To quote an editorial in the *San Antonio Express:*

> "As those enterprises shall take shape through the years, countless motorists who never heard of Mr. Arneson's name, and many a farmer tilling his acres watered by a harnessed river, will benefit from his far-sighted service."

In July, 1935, during the organization of the Works Progress Administration in Texas, it was realized that the selection of the first District Director would set the standard for the others who were to be appointed. Therefore, the State Administrator, recognizing Mr. Arneson's outstanding ability, both as an engineer and an executive, and knowing of the high place he had won for himself in his profession and among his fellow citizens, determined to induce him to take the first appointment as a District Director and to serve in that capacity for the San Antonio District. Although it meant a considerable financial sacrifice to Mr. Arneson, he was led by patriotic motives to accept the appointment, and he took the Oath of Office as District Director on July 10, 1935. The San Antonio District Office under his direction was one of the best in the State and the Works Program which he supervised did credit to the efforts of the Federal Government to relieve unemployment.

A number of times he asked the State Administrator to relieve him of his duties in order to enable him to return to his engineering practice, but he continued in this position until the planned consolidation of Works Progress Districts in Texas became effective, thereby making available another District Director who could take his place. Upon his insistence, the State Administrator reluctantly accepted his resignation effective July 15, 1937. However, this did not end his connection with the Works Progress Administration for, thereafter, his counsel and advice were often asked and gladly given.

Ed Arneson was well grounded in the theory and practice of Civil Engineering. Undoubtedly, had he lived the normal span of life, his work would have attracted greater attention, and his reputation as an engineer would have spread further over the country. But, to his intimates, it was in the rôle of a citizen that he made his greatest contribution to society. He had an inquiring mind, was ever a student and a gentleman, and his interests were broad, covering literature, art, music, and general culture. He had mastered the Spanish Language, was fast becoming familiar with French, and was a student and lover of Greek culture.

His thoughts and opinions were sound, and he was the type of man with whom one could differ radically and yet highly respect his position. While he adhered with fidelity to his opinions in fundamental matters, he always had an open mind for opposite arguments and would not hesitate to compromise on non-essentials or even change his opinions when argument convinced him he was wrong. He was a man who worked intently and played joyously, and he drew the deepest of devotion from the hearts of his numerous friends. In addition to the many other sides of his well-rounded personality Mr. Arneson was a student of history. His mental equipment was replete with facts and relationships covering the salient features of Texas development and the influence of Spanish culture on the southwestern part of the United States. Several of his papers on this subject have been published in the *Southwestern Historical Quarterly*.

He was always ready and willing to assume his full share of civic duty, even at personal cost. Mr. Arneson was of that type—all too few in any community—on which opposing political and civic factions were willing to rest their case and agree with his decisions as an arbitrator. His character can best be summarized by stating that he was the kind of a man that any one could point out to the young engineer as a safe guide to emulate.

Mr. Arneson was a member of the Rotary Club, Scientific Society, Technical Club, Yanaguana Society, and the First Presbyterian Church, all of San Antonio. He served the Rotary Club as Director for two years and was President in 1933. In 1935 he was elected District Governor of the 47th District of Rotary International. He was ever active in the affairs of the Texas Section of the American Society of Civil Engineers and was President for the year 1933–1934. His election as Director of the Society District No. 15 followed in 1936, which office he held at the time of his death.

As a Society officer he was conscientious in his work and faithful to his obligations. His breadth of vision enabled him to see the problems of the whole organization in a large way. Petty considerations had no place in his make-up. His ability to do real work was early recognized; for his entire term he took his full share of the arduous responsibilities as one of the Committee on membership qualifications. He served as member and finally as Chairman of the Board's Committee on Districts and Zones.

This capacity for seeing that a job was done, and done well, earned him the respect of his fellow Board members, while his delightful disposition and personality gained their affection. On those occasions when he took part in open discussion his grasp of the question at issue was always evident. No Board member had a more respectful hearing. His standing was evidenced in the tribute after his death adopted by the Board, as follows:

> "*Whereas* the Board of Directors of the American Society of Civil Engineers has been shocked to learn of the death, on December 7, 1938, of its fellow Director, Edwin P. Arneson; and
>
> "*Whereas* Mr. Arneson's death while still in the prime of life has removed one who had ahead of him many years of usefulness to the Society and to the profession at large; and
>
> "*Whereas* the Board has found him to be a most active and valued co-worker in all its affairs, with the interests of the Society always at heart; and
>
> "*Whereas* his character and friendliness have earned for him the esteem and affection of his fellow members of the Board,
>
> "*Now, therefore, be it resolved* by this Board, assembled in meeting at New York City this day, January 16, 1939, that it records its warm regard for its late associate, and its deep sorrow for his loss; that it extends its sympathy to his family, and directs that this resolution be spread on the minutes of the Board, and that a copy be forwarded to Mr. Arneson's family."

He was married to Anita Park at Bryan, Tex., on April 26, 1916, and this union was blessed with three children, Edwin Park, Lily Anita, and Richard Owen.

Mr. Arneson was elected an Associate Member of the American Society of Civil Engineers on May 12, 1919, and a Member on March 28, 1932.

CYRUS CATES BABB, M. Am. Soc. C. E.[1]

DIED OCTOBER 2, 1937

Cyrus Cates Babb was born June 18, 1867, at Portland, Me., the son of Cyrus Knap and Mary Lucretia (Judkins) Babb. He was of English and

---

[1] Memoir prepared by a Committee of the North Carolina Section, consisting of C. L. Mann, George H. Maurice, and W. M. Piatt, Members, Am. Soc. C. E.

Welsh descent. On the English side he was descended from Governor Joseph Dudley, of Massachusetts, and from Lieutenant James Peabody who came over in the *Planter* in 1635. It is not certain when his Welsh forebears arrived in this country, but it is known that James Babb bought land and settled in Westbrook, Me., in 1735.

After a High School education obtained at the English High School, at Boston, Mass., he was graduated from the Massachusetts Institute of Technology, in 1890, with the degree of Bachelor of Science.

During his college course, in 1887, Mr. Babb had employment on a preliminary railway survey between Rockland and Rockport, Me., and, during 1888, he served as Transitman under Mr. Gilbert Hodges on street railway work.

After his graduation in 1890, he obtained a position with the United States Geological Survey, and thus entered into his life work on hydrographic, reclamation, and water-power projects. With the exception of the summer of 1894 which was spent traveling in Europe, Mr. Babb remained with the Survey until 1904, as Hydrographer and Topographer, and traveled throughout the entire United States establishing gaging stations and enlisting the interest of local engineers, under the direction of the late Frederick Haynes Newell, M. Am. Soc. C. E., then Head of the Hydrographic Division. He established more gaging stations in this country than any other man in the Hydrographic Division. One—Babb, Mont., on Saint Mary's River—was named after him and is still in operation. During the fall and winter of 1898–1899, he made a daring reconnaissance survey of the Gila River Canyon. This was accomplished with a small pack-train outfit which struggled for days through the boulder-strewn canyon bottom, alternating with quicksands, the only human beings encountered being a few Apache Indians. It was on this trip that Mr. Babb made the preliminary survey for the San Carlos Dam site, on which, twenty years later, was built the Coolidge Dam.

Following this work he was in charge of surveys and investigations in Utah and Montana for water supply and irrigation projects, so that when the long-range planning of Mr. Newell bore fruit in 1902 as the Reclamation Act, Mr. Babb was transferred to the United States Reclamation Service as Project Engineer in charge of all designs for reservoir dams, outlet gates, canal sections, and estimates of cost. He had charge of the St. Mary-Milk River (Montana) Project, including extensive field surveys, borings, and all designs for the irrigation of 150 000 acres, involving the expenditure of upward of $6 000 000. While on this work he joined the Masonic Malta Lodge during 1904.

From 1909 to 1911, he was engaged as District Engineer of the U. S. Geological Survey, on detail to the Storage Commission of the State of Maine, and, in the latter year, became Chief Engineer of this Commission, continuing in this capacity through 1914. His duties included the investigation of the water resources of the State, examinations and estimates of the water powers and storage possibilities, and the preparation of the Annual Reports of the Commission. This work increased his interest in water power and resources so much that they became his chief interest during the future years of his life. He was a member of the Maine Association of Engineers, and served as its President in 1911, later becoming an Honorary Member.

In 1915 Mr. Babb opened an office in Augusta, Me., and began private practice as a Consulting Hydraulic Engineer. His activities included Consultant on water supply of towns in Maine; valuation of water-works property for a rate revision contest; detailed reports on a number of large power and storage prospects for certain New York financial interests; Court Expert in cases involving water-power questions; a noteworthy design for a hollow concrete dam on a glacial drift foundation, etc.

In 1917, he moved to Granite Falls, N. C., and continued his hydraulic and general engineering practice. He served as Consulting and Designing Engineer for a number of hydraulic and power developments, manufacturing companies, and municipal water supply and sewerage systems. He was Consulting Engineer for the Rhodhiss Manufacturing Company, and the E. A. Smith Manufacturing Company, Rhodhiss, N. C., manufacturers of cotton goods, on one of the earlier modern hydraulic power and electrification developments in the South. He designed and superintended the construction of the water supply and sewerage systems for Blowing Rock, N. C., and the 18-hole golf course and subdivisions for the Green Park Company, in Blowing Rock.

In January, 1929, Mr. Babb returned to service with the Government in the United States Engineer Office, at Charleston, S. C., and, later, at Norfolk, Va., as Senior Hydraulic Engineer, United States Corps of Engineers, in charge of water-power and flood-control investigations. He covered the resources of the Santee River, in North Carolina and South Carolina; the Yadkin-Pee Dee River, in North Carolina and South Carolina; the James River, in Virginia; the Roanoke River, in North Carolina and Virginia; and the Susquehanna River, in New York State and Pennsylvania.[2]

After the completion of this assignment, he was transferred to the Baltimore, Md., Engineer District, and after the appointment of the National Resources Committee, worked for that Committee as Associate Consultant on the Drainage Basin Studies, first at Durham, N. C., and, later, at Columbia, S. C., under William M. Piatt, M. Am. Soc. C. E., Regional Consultant. After the completion of the field work in this District, he was transferred to Washington, D. C., to assist in the preparation of the final text of that part of the report of the Water Resources Committee under the title "Drainage Basin Problems and Programs."

In December, 1936, Mr. Babb resigned to take up his consulting engineering practice, being retained by the Rhodhiss Manufacturing Company for enlargements to its plant. He was also engaged in extensive investigations and estimates for possible hydraulic power developments in the Piedmont Region of North Carolina.

Gerard H. Matthes, M. Am. Soc. C. E., one of Mr. Babb's associates in the U. S. Geological Survey and Reclamation Service, writes as follows:

"It was always a pleasure to meet Babb for he was a royal good fellow to be with out in the wilds. He was a 'good sport' and had the knack of adjusting himself to circumstances and making the most of any situation. His sunny disposition and true-blue character always managed to win a way for him even in difficult situations. * * * To my mind, the outstanding traits of Babb's character were faithfulness and dependability. He truly possessed a 'New England Conscience' and those who roughed it with him in the Far West learned to appreciate those sterling qualities."

---

[2] Under the provisions of H. R. Doc. No. 308, 69th Cong., 1st Session.

During the World War, Mr. Babb was an Associate Member of the Legal Advisory Board, and Chairman of the Red Cross and War Savings drives for Caldwell County, North Carolina. He was a member of the Granite Falls School Board from 1921 to 1925, serving as Secretary-Treasurer during the building of the new schoolhouse.

Tennis had been Mr. Babb's chief sport until of late years, when gardening and the reading of contemporary authors became his chief recreation.

He was married, at Lutherville, Md., on March 7, 1906, to Mary Grace Crowther, who died in July, 1938. Mrs. Babb, with two children, Mrs. John P. (Katharine) Rabb, and Dr. Dudley C. Babb, survived him.

At the time of his death, he was an Honorary Member, Maine Association of Engineers (Past-President, 1915) and a Member of the American Geophysical Union. He had contributed papers[3] and discussions to the publications of the Society.

Mr. Babb was elected a Junior of the American Society of Civil Engineers, on February 2, 1892; an Associate Member on February 3, 1897; and a Member on March 1, 1904.

CHARLES LELAND BATCHELDER, M. Am. Soc. C. E.[1]

Died January 18, 1939

Charles Leland Batchelder was born in North Reading, Mass., on January 1, 1887. He was the son of Leland D. Batchelder and Mary (Putnam) Batchelder who were of old New England stock, their forefathers having landed at Salem, Mass. Both parents were greatly interested in educational and church work, and the Leland D. Batchelder School of North Reading was named in honor of the father in recognition of his outstanding interest in public education.

Mr. Batchelder's boyhood was spent in North Reading. He attended the Massachusetts Institute of Technology, at Boston, Mass., from which he was graduated with a Bachelor of Science degree in 1909.

Upon graduation, he at once secured employment under the City Engineer of Lowell, Mass., where he served from 1909 to 1912 as Instrumentman engaged in the design and construction of sewers, water mains, water-supply structures, and various bridges built by the city.

---

[3] *Transactions*, Am. Soc. C. E., Vol. XXVII (1892), p. 21; and, also, Vol. XXVIII (1893), p. 323.

[1] Memoir prepared by E. V. Willard and C. G. Paulsen, Members, Am. Soc. C. E., and C. H. Prior, Assoc. M. Am. Soc. C. E.

From 1912 to 1918, Mr. Batchelder was employed by the United States Geological Survey. Starting as Junior Engineer, he was assigned in the central office in Washington, D. C., where he spent one year. He was next assigned in the Survey's district office in Salt Lake City, Utah, and then in the Oregon district with headquarters in Portland.

In recognition of the high quality of his work, he was soon promoted to Assistant Engineer in which position he took an active part in the design and construction of structures and equipment for stream-flow measurements, as well as in the computation and compilation of stream-flow records in the areas covered by his assignments.

In 1918 he resigned from the Geological Survey to accept a position as Auditor and Chief Cost Accountant for the Warm Springs Irrigation District at Vale, Ore., where he was responsible for auditing the construction and operation costs of this district, the construction of which cost more than one and one-quarter million dollars. Because of his outstanding ability to make friends and reconcile conflicting view-points of opposing factions within the district, as well as his recognized engineering ability, he was soon appointed its Secretary and Manager. This position not only carried the responsibility of managing the district, but also included responsibility for the design and construction of the many irrigation head-gates and diversion dams needed for this project, and the task of instructing water users as to the proper and economical use of water. His friendly and tolerant attitude toward those with whom he came in contact, and his fair and impartial administration, brought to him the respect of all who were interested in the project and made for him a host of personal friends.

In 1928 Mr. Batchelder returned to the United States Geological Survey as Hydraulic Engineer in charge of field investigations in connection with international flood control problems on the Roseau River in Minnesota. Soon thereafter a district office of the Geological Survey was established in St. Paul to conduct the above international work and the general surface water investigations in Minnesota in co-operation with the State, and because of his excellent organizing and administrative ability, Mr. Batchelder was designated district engineer in charge of the work. In addition, he supervised similar co-operative activities in parts of North Dakota, South Dakota, Wisconsin, and Iowa.

Mr. Batchelder was unstinting in his efforts in helping to solve the many complex water problems of the district. Laying the ground work for a long-time study of stream flow in his district, he proceeded in a most efficient and thorough manner to carry on this program of work so as to produce results of the greatest value in connection with the water problems of the State. He became an authority on problems of stream flow, and his willingness to co-operate with various local and Federal agencies was very effective in producing vital data for the solution of these water problems. These data were used in preparing plans to alleviate water shortage in the Red River of the North during drought periods, and water-conservation programs throughout the district.

Mr. Batchelder was greatly interested in the improvement of stream-gaging equipment, and various improvements in the design and assembly of equipment for making discharge measurements from boats were made under his direction. Many of his suggestions were incorporated in the designs for other types of stream-gaging equipment.

His friendly and understanding attitude toward his associates was appreciated by all who worked with him, and he made many contributions to engineering and hydrology. His untimely passing is a distinct loss to the profession.

Mr. Batchelder was married on December 4, 1912, to Esther Emerson who, with a daughter, Mrs. Charles Bodey, and a son, Charles L. Batchelder, Jr., survives him. He is also survived by a brother, Stewart P. Batchelder, and two sisters, Sarah and Elizabeth Batchelder.

Mr. Batchelder was elected a Member of the American Society of Civil Engineers on March 16, 1936.

RICHARD BIRBECK, M. Am. Soc. C. E.[1]

DIED DECEMBER 6, 1937

Richard Birbeck, the son of John and Katherine Birbeck, was born at Lawrence, Kans., on June 2, 1861. His parents, both of whom were born in England, were among the early pioneer farmers who went to Kansas prior to the Civil War. They settled on a farm near Great Bend in the south central part of the State in 1866, and there Richard Birbeck spent his hard-working youth in comparative poverty. Educational facilities were very limited, but he entered the Preparatory Department of the University of Kansas in 1880 and continued his preparatory and college work without interruption. He was graduated in the Class of 1886 with the degree of Bachelor of Science in Civil Engineering.

The story of his hard fought battle to secure an education is an interesting one. Mr. Birbeck found a room over the largest livery stable in town and, with a small stipend for taking care of livery service night calls, he secured the job of lighting the gas street lamps, and for six years was a familiar figure running miles around the town with his short ladder on his shoulder.

He was a hard-working, conscientious student who did good work, made many friends, but who had no social life other than that of the class-room and a few college extra-curricular activities. He was always genial, helpful, and ambitious, and was well liked by his classmates, although his financial condition was such that his studies and his work occupied him fully.

After his graduation, Mr. Birbeck was employed by the Santa Fé Railroad Company and remained in that service until December, 1887. From January to July, 1888, he was County Surveyor of Stafford County, Kansas, which position he left to enter the service of Baxter L. Brown, M. Am. Soc. C. E., who writes of him as follows:

---

[1] Memoir prepared by A. C. Reed, Esq., Port Orange, Fla., Henry Earle Riggs, President, Am. Soc. C. E., and Baxter L. Brown, M. Am. Soc. C. E.

"In August, 1888, I was organizing a party to make a preliminary and location survey for the Kansas City, Wyandotte & Northwestern Ry. from Seneca, Kansas, to Beatrice, Nebraska, and the Superintendent urged me to give a job to a young man who had recently graduated from Kansas University, and who used to take care of his horse when in Lawrence. I consented, and the next day Dick Birbeck showed up.

"It did not take me very long to learn that Dick was well qualified to be pushed ahead as fast as circumstances would permit, and it was always my pleasure to have him working for me whenever possible."

According to the files kept by Mr. Brown, the following is a record of Mr. Birbeck's work from August, 1888, to March, 1901, when he left for Cuba: August, 1888, to February, 1890, Topographer and Draftsman, Kansas City, Wyandotte and Northwestern Railway Company; April to June, 1890, Assistant Engineer, Bridge and Building Department, Missouri Pacific Railroad Company; June, 1890, to May, 1892, Surveyor and Draftsman in Southeastern Kentucky for the Kentucky Land and Improvement Company (later, known as the Central Appalachian Company, Limited); June, 1892, to August, 1895, with the Watts Steel and Iron Syndicate, in Tennessee; also Engineer of mine work, etc., and Superintendent of mine for six months; September, 1895, to May, 1896, Transitman and Draftsman on the relocation and reconstruction of the St. Louis, Chicago, and St. Paul Railroad, from Alton to Grafton, Ill. (this road later became a part of the Chicago, Peoria and St. Louis Railroad); May, 1896, to January, 1897, Draftsman and Topographer, Shelbyville Southern Railway from Shelbyville, Ill., to Altamont, Ill. (when this work was completed, it became a part of the Chicago and Eastern Illinois Railway); and January, 1897, to March, 1901, with the St. Louis, Iron Mountain and Southern Railway Company, on office engineering work.

In March, 1901, Mr. Birbeck left the United States and entered the service of the Cuba Company and the Cuba Railroad Company. Mr. A. C. Reed, of the Cuba Company, tells of these twenty-two years of his life:

"From March, 1901, to September, 1923, he was with the Cuba Co., and the Cuba R. R., except a short period in 1919 and 1920 when he secured leave to go to the Atlantic Fruit Co. as Chief Engineer in charge of design and construction of railroad lines and dock facilities. During the period that he was with the Cuba Company and the Cuba R. R., he was Assistant Chief Draftsman, Construction Engineer, Office Engineer, and Chief Engineer.

"For many years he took all of his vacations by returning to the field on location or construction of branch lines or other projects either for his own company or for the many sugar companies. His services were in great demand by the various sugar companies for their yard and mill track-layouts, and for the location of railway lines coming in from the fields to the mill.

"In September, 1923, he retired, moved to New York, and did only such work as the Cuba Company requested until his death on December 6, 1937."

Mr. Birbeck was married on August 6, 1896, to Ellora Landoun, of Missouri, who died on April 7, 1900. On his return to the United States from

Cuba he was married to Mrs. Jeannette Deppe, a sister of his first wife. He is survived by his widow and by a son, Gratz Birbeck, a sister, Mrs. Jennie Umphrey, and two nieces, Catherine (Umphrey) Shepard and Patrica Jane Shepard.

He was a member of the Masonic Order and of the Society of American Military Engineers.

Those who had been associated with Richard Birbeck at any time during his long life, remember him as a hard-working, thoroughly reliable engineer who was intensely loyal to his employers and to his friends. He found great pleasure in helping young engineers to get a start in the profession and for this he will be long remembered by engineers who are resident in many countries.

Mr. Birbeck was elected a Member of the American Society of Civil Engineers on December 3, 1928.

HENRY ROBINSON BUCK, M. Am. Soc. C. E.[1]

DIED AUGUST 11, 1934

Henry Robinson Buck was born on September 14, 1876, in Wethersfield, Conn. He was descended from distinguished colonial stock, and his ancestors were among the earliest settlers in Connecticut. A graduate of Yale University, at New Haven, Conn., in the Class of 1896, Sheffield Scientific School, he was throughout his life a loyal alumnus, taking a special interest in all the activities and reunions of the University.

As might be expected from one of his historic background, Mr. Buck was intensely patriotic. An opportunity to exhibit this loyalty occurred early in his professional career; he served in the United States Navy during the Spanish-American War, being one of the crew that made a memorable voyage in one of the old Monitors from Boston Harbor to Philadelphia, Pa. He was an Associate member of the Naval Consulting Board in 1915, and State Director of the Industrial Preparedness Board in 1916.

His life was devoted to work throughout his native State in the fields of general and sanitary engineering. As Chief Engineer for the State of Connecticut, from 1905 to 1923, he remonumented the New York and Massachusetts boundaries of the State, and served as Engineer for the State Armory Board at Hartford, Conn. During the period from 1923 until his death he was Chief Engineer for the Emergency Conservation Work in Connecticut, having charge of all construction work undertaken in the C. C. C. Camps. He was the engineer member of the State Factory Waste Commission. He was a member of the Park Board in the City of Hartford, where he lived and carried on his business. These and many other public responsibilities were discharged in addition to his own work as a Consulting Engineer.

---

[1] Memoir prepared by Edward Eastman Minor, M. Am. Soc. C. E.

Some of his outstanding work on sewage treatment was done for the Connecticut towns of Watertown, Wethersfield, New Canaan, and Putnam. In the design of sewage systems, the following projects were designed and carried out by him—sewage systems for Wethersfield, Hamden, Watertown, West Hartford and Windsor, all in Connecticut. In connection with State Institutions, both sewage and water systems were designed and constructed by him throughout the State.

An engineer serves his profession also in the various technical societies covering his field. Mr. Buck gave generously of his time for this purpose. He was President and later an Honorary Member of the Connecticut Society of Civil Engineers; a charter member of the American Institute of Consulting Engineers and on its Executive Committee; Vice-President of the New England Water Works Association; and one of the founders of the Hartford Engineers Club.

One of the most distinguished of such services was given on behalf of the Society. District No. 2, comprising practically the entire New England States, had had many eminent representatives on the official Board of the Society, but it had been some years since such representation had been filled by a member from Connecticut. Mr. Buck's many professional friends advanced his name for this service, thus indicating their high estimate of his character and professional standing. Accordingly, he was elected in January, 1931, as Director, serving for the following term of three years.

He soon gained for himself a position of prominence and respect in the Board deliberations. Recognizing his ability, he was called upon to serve on a number of important committees, including that on Technical Procedure for two years. In particular, however, his great contribution was in connection with the Society's publications. For all three years of his term as Director, he served on this important Committee, being a chairman in his last year, 1933.

On this Committee he was permitted to be of unusual service to his profession. The publication, "Civil Engineering," had just been started and many problems of procedure and policy were actively before the Committee. On such his judgment was sound; and he had the strength of his convictions. During the time of financial stringency, he was a tower of strength. His fairness and judicious temperament made him an ideal chairman of the Committee. His tact in handling difficult situations made for the smooth handling of Society publications during this critical period.

The fine record that he made on this work was recognized by a tribute to his memory by his associates on the Publications Committee, who spread on the Minutes of the Board the following "Appreciation of Henry R. Buck:

> "All activities of the Society, but particularly the publication work, suffered a severe loss in his death. During all his term of office on the Board of Direction, Mr. Buck was a member of the Publications Committee, being Chairman in 1933. He made an ideal chairman, being faithful in every detail of his work and vitally interested in all Society publications. An enthusiastic supporter of all the best interests of the Society, he endeared himself especially to the members of the Publications Committee,

who are a unit in feeling for him personally the greatest of respect and for his loss the deepest of sorrow. Every aspect of the Society work is the richer for the sincere efforts of Henry R. Buck."

An engineer who combined technical skill with executive ability, whatever task he undertook was carried through with marked ability, his enthusiasm and confidence inspiring those associated with him. In addition to his engineering proficiency, his integrity of character, broadmindedness, and sympathetic understanding made his services of exceptional value both to the State, his clients, and his friends.

Mr. Buck found relaxation in all outdoor activities. He was an ardent mountain climber and a member of the Appalachian Mountain Club. The writer recalls being in camp at the foot of Katahdin in Maine with a group of Appalachian Club members when Mr. Buck arrived. He immediately became the leader and driving force of the party. This enthusiasm and leadership was always in evidence in whatever activity he was engaged.

Among his social activities, Mr. Buck was a Thirty-second degree Mason, and Past Master of Hartford Lodge AF and AM No. 88. He was also a member of the Hartford Rotary Club, the Twentieth Century Club, the University Club of Hartford, the Graduates Club of New Haven, Appalachian Mountain Club of which he was Vice-President in 1927, the Connecticut Forest and Park Association as Vice-President and Scout Commissioner, Charter Oak Council, B. S. A. 1924–1928.

Mr. Buck was married on December 3, 1901, to Mary Ladoyette Wolcott. He is survived by his widow; two sons, Henry Wolcott and Robinson Dudley Buck; and one daughter, Elizabeth Roswell (Mrs. Dallas W. Dort). He was killed in an automobile accident on Avon Mountain, just west of Hartford, on August 11, 1934, and was buried in Cedar Hill Cemetery at Hartford.

Henry Robinson Buck was elected a Junior of the American Society of Civil Engineers on June 5, 1900; an Associate Member on October 4, 1905; and a Member on February 4, 1908.

EDWARD ABRAHAM BYRNE, M. Am. Soc. C. E.[1]

Died December 6, 1938

Edward Abraham Byrne was born in New York, N. Y., on January 27, 1864, the son of Frederick John and Susan Mary (Power) Byrne, and the descendant of an old New York family of Irish heritage. Educated in the Public Schools of the city, he was graduated from the College of the City of New York in 1884. Thus, by ancestry, birth, and education he was preeminently a New Yorker, and the love he bore for his city was revealed throughout his strenuous life.

---

[1] Memoir prepared by Isidore Delson, Assoc. M. Am. Soc. C. E.

Mr. Byrne began his engineering career in 1886 with the New York Aqueduct Commission on the construction of the Croton Water Supply System. It is of interest that on this project he met the late Robert Ridgway, Past-President and Hon. M. Am. Soc. C. E., who also was destined to become a distinguished engineer and an outstanding civil servant.

From 1889 to the close of 1897, Mr. Byrne worked on highways and bridges for the old Department of Public Works of New York City.

On January 1, 1898, he joined the Department of Bridges and began a striking and noteworthy service which ended in November, 1933, with his resignation from the position of Chief Engineer of the Department of Plant and Structures (the successor of the Bridge Department), in order to assume the duties of Chief Engineer of the Triborough Bridge. His thirty-six years of service in the Department of Bridges, and its successor, the Department of Plant and Structures, may be divided into two periods. From 1898 to 1912 he was in charge of bridge construction and maintenance. During this period he supervised the construction of the Willis Avenue Bridge over the Harlem River, Vernon Avenue Bridge over Newton Creek, Borden Avenue Bridge and Hunters Point Bridge over Dutch Kills, and the old Flushing Bridge over Flushing River. The second period began with his assumption of the office of Deputy Chief Engineer in 1912, followed by his appointment as Chief Engineer in 1915. At the close of the World War, the Department of Plant and Structures began a period of intense activity which was cut short only by the depression of 1930. Not less than fifteen new bridges of major importance, of which ten were of the bascule type, were built in this period. In addition, under Mr. Byrne's direction, the Department designed and constructed a number of large incinerator plants and many other structures for the several departments of the City. He increased the capacity of the Manhattan and Queensboro Bridges over the East River by the construction of additional vehicular roadways on their upper decks.

Mr. Byrne was greatly preoccupied with the study of traffic facilities. As far back as 1916 he conceived the idea of the Triborough Bridge to link the Boroughs of Manhattan, Bronx, and Queens. He fostered this idea until he thought the time was ripe for its materialization. The actual work on the foundations and anchorages was begun in 1929 under his direction, while Chief Engineer of the Department of Plant and Structures.

Then, in November, 1933, upon the organization of the Triborough Bridge Authority, he became its first Chief Engineer. There is no doubt that Mr. Byrne looked upon the construction of the Triborough Bridge as the culmination of his career, and there is pathos in the fact that he was forced to relinquish his post in February, 1934, only several months after he had entered upon it with such high anticipation.

Primarily Mr. Byrne was an engineer and executive, and because of character, integrity, and devotion, held his position, independent of politics, throughout successive administrations. The administration headed by Mayor LaGuardia assumed office on January 1, 1934, with a mandate for a "clean sweep," and the complete reorganization of the Triborough Bridge Authority was among the changes which followed. It is fitting that credit for the initiation of the Triborough Bridge should be accorded Mr. Byrne.

Another instance of Mr. Byrne's active concern with traffic facilities is his advocacy of a vehicular tunnel from the Battery to Hamilton Avenue, in Brooklyn, N. Y., by way of Governors Island. He prepared preliminary plans for this project which was an exceedingly live story in 1939. In 1929, also, he prepared preliminary plans and estimates for a vehicular tunnel under the East River from Manhattan Island at Thirty-eighth Street to the Borough of Queens.

Mr. Byrne was a Consulting Engineer of the New York State Bridge and Tunnel Commission, and of the Camden-Philadelphia Bridge. He was a Past-President of the Society of Municipal Engineers of New York; a Past-President of the Kings County Chapter of the New York State Society of Professional Engineers; a member of the Brooklyn Engineers Club, and of the Catholic Club. He was a trustee of the Greenpoint Savings Bank.

Mr. Byrne was married to Elizabeth Mary Dillon in 1903. She died in 1912, leaving him two young sons. Mr. Byrne did not remarry. His heart and soul was with his children, and he participated in their lives until they were safely through college.

Those associated with Mr. Byrne realized that he had an unusual personality. He possessed power, energy, and a driving force which overcame apparently unsurmountable obstacles. The uncompromising integrity with which he conducted his responsible office was felt throughout his department. Beneath an exterior which years of command and responsibility had rendered somewhat stern, he fostered a kindly, generous, and charitable disposition —always ready with help and sympathy for fellow humans in distress. His engineers will remember the pleasure he derived from the genial luncheon intermissions when out on some job. No matter how serious the business might have been, Mr. Byrne would relax completely and, with a generosity which became proverbial, play the host to his party.

He was far from being a recluse. He was fond of the theater, particularly musical comedy. He delighted in attending football games and other sports. When his sons were at the University of Notre Dame, in Notre Dame, Ind., he attended religiously all the Notre Dame games and was as enthusiastic about them as any under-graduate.

Mr. Byrne was deeply religious and loyally attached to the Roman Catholic Church. Withal, he possessed the gift of social, political, and religious tolerance, characteristic of the best type of New Yorker who has grown up in contact with the populous amalgam of the astounding city.

Mr. Byrne died in Rye, N. Y., on December 6, 1938, at the home of his son Edward. He was buried in Calvary Cemetery, in the Borough of Queens, Long Island, and thus his last ride was over the bridge which played so great a part in the drama of his last years.

He is survived by two sons, Edward and George Dillon; and by two granddaughters, Elizabeth and Barbara Byrne, the children of Edward.

Mr. Byrne was elected a Member of the American Society of Civil Engineers on April 16, 1918.

FRED EDWARD CALDWELL, M. Am. Soc. C. E.[1]

DIED JANUARY 2, 1939

Fred Edward Caldwell was born at Heuvelton, N. Y., on August 9, 1879, the son of Thomas and Ruth (Smithers) Caldwell. He attended the Public School in Heuvelton, and later, from 1897 until 1900, he attended the State Normal School at Potsdam, N. Y. In 1901 he enrolled as a Civil Engineering student in the Clarkson College of Technology at Potsdam, where he studied until 1904. Each summer vacation he was employed as Transitman and Recorder with the United States Lake Survey, first on the St. Lawrence River and later at Green Bay, Wis., on Lake Michigan.

In 1904 Mr. Caldwell was employed by the firm of Williams, Proctor and Potts as Resident Engineer on the construction of sewerage systems and sewage disposal plants at various places, the more important of which were at Havre de Grace, Md., Newton, N. J., and Morristown, N. J. He also assisted in the preparation of plans for sewerage systems for Waverly, N. Y., Leetonia, Ohio, and Chatham, Ridgewood, and Washington, N. J. In 1910 Mr. Caldwell became associated with the Ansonia Manufacturing Company of New York, N. Y., as Designing Engineer on automatic sewage control mechanisms for disposal plants.

In September, 1911, he returned to the practice of sanitary engineering as Chief Engineer to Clyde Potts, M. Am. Soc. C. E., Consulting Engineer of New York City. He remained in this position for eight years, acquiring an intimate knowledge of all projects that passed through the office. Sewerage systems were built at Salem, N. J., West Haven, Conn., Verona, N. J., and Nazareth, Pa. He assisted in the preparation of many reports on proposed projects and prepared plans for sewerage systems for several New Jersey towns in the valley of the Rockaway River above the water-supply reservoir of Jersey City at Boonton, N. J. These included Dover, Rockaway, and Boonton. A trunk sewer was designed to collect the sewage of these towns and convey it to a point below the Jersey City Reservoir where it would receive complete treatment. Another similar project upon which Mr. Caldwell did the early development work and made preliminary plans was a trunk sewer to convey the sewage from the towns along the Rahway River to a disposal plant at tide-water. These towns were Rahway, Cranford, Westfield, and South Orange. This project, with some change in the towns participating, was constructed in the late 1920's.

From March until December, 1918, he was engaged on war work as Sanitary Engineer at the Hammonton, N. J., shell loading plant of the United States Ordnance Department. A complete system of sewers and sewage disposal was constructed, as was also a water-supply and fire-protection system. At the conclusion of the war Mr. Caldwell was made Promotion Engineer on concrete products with the Portland Cement Association which was then developing from a back-yard enterprise, producing a product of questionable merit, to the modern concrete products plant of to-day. Mr. Caldwell remained with the Association until 1922 and it was through his efforts that the first high production automatic machines for the production of both concrete building units and concrete pipe were introduced in the New York area. Until his death all of Mr. Caldwell's efforts were directly or indirectly toward better concrete, new uses for concrete, and the securing of recognition of the merits of concrete products by the trade.

---

[1] Memoir prepared by Benjamin F. Batchelder, Assoc. M. Am. Soc. C. E.

In 1922 he acquired an interest in the Springfield Sand and Tile Company, of Springfield, Mass., and became Vice-President and Manager. Through his efforts the use of concrete units was greatly increased in this section by the production of a dependable product, and building codes were soon opened to their use in all classes of construction. Severing his connection with this Company in 1928 he became Sales Engineer in the New York area for the Keystone Portland Cement Company which had just started production of one of the first high early-strength Portland Cements. He remained in this position for two years and secured a wide use of this cement in the concrete products industry.

In 1932 Mr. Caldwell acquired an interest in the Haller Testing Laboratory at Plainfield, N. J., and as Vice-President of the Company continued his interest until a short time before his death. In 1936 the Company organized the New England Testing Bureau with offices at Boston, Mass., to accommodate their rapidly expanding business in that section, and Mr. Caldwell became Vice-President of this subsidiary.

He was married to Bessie M. Harris at Newton, N. J., on February 26, 1908. They had one child who died in infancy.

Mr. Caldwell was a Mason, an Elk, and a member of the Engineers Club of New York City. During his college days he was active in athletics and particularly excelled in football and baseball. He had a wide circle of friends and business associates, all of whom admired and respected him.

Mr. Caldwell was elected a Junior of the American Society of Civil Engineers on April 3, 1906; an Associate Member on February 1, 1910; and a Member on May 12, 1919.

JAMES EDWARD CARROLL, M. Am. Soc. C. E.[1]

DIED JANUARY 25, 1939

James Edward Carroll was born in Austin, Minn., on August 11, 1870, the son of Patrick Bernard and Margaret (MacMahon) Carroll. He received his High School education in Minneapolis, Minn., and attended the University of Minnesota, in Minneapolis, from 1886 to 1891, completing the Civil Engineering course with the exception of one term.

---

[1] Memoir prepared by George M. Shepard, M. Am. Soc. C. E.

Mr. Carroll began his engineering career in 1885 as a Rodman and Draftsman with the late George W. Cooley, who was later State Highway Engineer.

During his university course he was employed as Chainman and Assistant Transitman by Hennepin County, Minnesota; as Timekeeper and Rodman for the Great Northern Railway Company; as Levelman for the Chicago, Milwaukee and St. Paul Railway Company; and as Chief of resurvey crew for the Northern Pacific Railway Company on its Dakota, Montana, and Yellowstone Divisions.

Upon leaving school in 1891 he became Scaler and Assistant Yard Foreman for the N. P. Clarke Lumber Company in Minneapolis. In 1893 he joined the engineering staff of the City Engineer of Minneapolis and began the long and creditable career of municipal engineering, both in public service and private practise, which terminated only a few weeks before his death. Beginning as a Draftsman and Levelman in the Bridge Department, he advanced to the position of Street Paving Engineer.

Mr. Carroll was appointed City Engineer of Crookston, Minn., in 1903, and served in this capacity, as well as in the capacity of Consulting Engineer to adjacent cities, until 1912. In the latter year he was appointed Assistant Commissioner of Public Works of St. Paul, Minn., and served as such until 1914 when the position was abolished. He was then appointed Assistant Chief Engineer of the Department of Public Works of St. Paul and Superintendent of Construction and Repair. He continued in this position until 1923, except for his absence during the World War, and again served in the same position from 1932 to 1934.

Following his resignation from the city service in 1923, he formed a partnership with the late Oscar Claussen, M. Am. Soc. C. E. This partnership, under the name of the Claussen and Carroll Engineering Company, with offices in St. Paul, engaged in a general consulting practise, specializing in municipal engineering matters. This partnership continued until the death of Mr. Claussen in 1932. In 1934 Mr. Carroll formed the James E. Carroll Engineering Company and continued his consulting practise up to within three or four weeks of his death.

In 1917 he entered the Engineer Corps of the United States Army and was commissioned a Major, serving 1 yr in France. He spent the greater part of this time as commanding officer of the 527th Engineer Service Battalion, taking part in the St. Mihiel and Meuse-Argonne offensives.

Major Carroll was a student of municipal engineering and allied subjects, and was the author of articles on "Cost Data—Drainage Engineering and Contracting" and "Tree Planting in St. Paul."

He was interested in the welfare and activities of World War Veterans and was one of the organizers and first commanders of Argonne Post, American Legion, in St. Paul. At the time of his death at the local Veterans Bureau Hospital, he was active in affairs of the Veterans of Foreign Wars.

Major Carroll was extremely fond of hunting, which formed his principal recreation. In the Fall of 1938, only two and one-half months before his death, he made his regular deer hunting trip and as usual "bagged his deer." His activity in public office for so many years and his long, successful practise give evidence of his personal integrity and professional ability. An engineer whose education was interrupted by the necessity of work, and whose early training was obtained by hard experience, Major Carroll through his years of experience acquired a knowledge of municipal problems which made his service invaluable to the communities he served. He was a member of the Catholic Church, and Delta Upsilon Fraternity.

In 1893 he was married to Frances Bayley of Minneapolis. She died in 1917. He is survived by three daughters, Frances, Adelaide, and Agatha.

Major Carroll was elected a Member of the American Society of Civil Engineers on June 23, 1916.

GEORGE B. CHRISTIE, M. Am. Soc. C. E.[1]

Died August 1, 1938

George B. Christie was born in Atlanta, Ill., on September 7, 1862, the son of James Rodney Christie, of Dover, N. H., and Miriam Hunt (Deaver) Christie, of Baltimore, Md. His father was of Scotch ancestry, and his maternal ancestors were among the early settlers of Maryland, who served in the War of the Revolution and the War of 1812. His father organized the 106th Company of Illinois Volunteers and served as its Captain during the Civil War. He was christened George B. McClellan Christie in honor of General George B. McClellan.

Mr. Christie received his early education in the public schools of Atlanta. Later, he entered the University of Illinois, at Urbana, Ill., and finished his Sophomore year in June, 1881. At that time he entered the service of the St. Louis, Fort Scott, and Wichita Railroad Company, in Kansas City, Mo., as Instrumentman on location. He followed railroad location and construction as Engineer in Charge until January, 1884.

He then became Assistant City Engineer of Omaha, Nebr. From February, 1886, to July, 1888, he was a member of the engineering firm of Rosewater and Christie, of Omaha. Victor Rosewater, the Senior Partner, later became a famous newspaper editor. This firm designed and superintended the construction of sewerage systems in Lincoln and Grand Island, Nebr., in Wichita and Atchison, Kans., and in other cities. Its members also made reports on many other enterprises.

In July, 1888, Mr. Christie and the late Jesse Lowe, M. Am. Soc. C. E., organized the firm of Christie and Lowe, Civil Engineers and Contractors, maintaining offices and residence in Chicago, Ill. The members of this firm constructed fifty miles of cable road in Denver, Colo., and in Brooklyn and New York, N. Y. In 1892 and 1893, they served as Engineers and Contractors for an underground electric railroad in Washington, D. C. Afterward, they built the masonry piers of the Bellefontaine Bridge for the Wabash Railroad Company, across the Missouri River near Bellefontaine, Mo. They also built

---

[1] Memoir prepared by A. D. Millard, Esq., Beardstown, Ill.

Sections I and K of the Chicago Drainage Canal, this being an exceptionally heavy job of rock cutting for which Mr. Christie designed special machinery and appliances.

For a number of years the firm of Christie and Lowe also included the late James O. Heyworth, M. Am. Soc. C. E., of Chicago (who, later, became a Contractor in his own right and was highly successful), and the late George A. Lederle, M. Am. Soc. C. E. Among the works performed by Christie, Lowe and Heyworth were the harbor works at Sabine Pass, Tex., and the Bear Trap Dam, on the Chicago Sanitary District Canal, at Lockport, Ill., which, however, was a part of the original contract of Christie and Lowe with the Sanitary District.

The work at Sabine Pass consisted of building a sea-wall at the mouth of the Sabine River where it empties into the Gulf of Mexico. This contract amounted to more than $1 000 000. The firm of Christie, Lowe and Heyworth also built four locks on the Black Warrior River, near Tuscaloosa, Ala. After the Sabine Pass contract was completed, the plant was shipped to Fernandina, Fla., where a contract was executed to build jetties at the mouth of the St. Marys River, for the United States Government. This was a contract for $1 500 000. The Sabine Pass work was finished in September, 1900, and the Fernandina work in the summer of 1904. Offices were established in 1904 at New Orleans, La., and during the succeeding period of eight years the firm built the sea-walls at Fort Gaines and Fort Morgan, in Alabama. It also built the jetties at the Southwest Pass, at the mouth of the Mississippi River, the latter work amounting to about $6 000 000. This particular piece of work is a monument to the skill and ability of Mr. Christie and his associates.

Mr. Lederle died during the period that the firm's offices were in New Orleans, and Mr. Heyworth withdrew from the firm when the Fernandina work was finished, thus leaving the partnership of Christie and Lowe as it was originally. The jetty work at the mouth of the Mississippi River, at Southwest Pass, was the last large work performed by Christie and Lowe, after which the office was moved to Beardstown, Ill., to develop the firm's large land holdings there. After the death of Mr. Lowe, in 1918, Mr. Christie continued to reside in Beardstown giving his time and attention to these interests until about 1932, when he moved to Ottawa, Ill., and from there to Mobile, Ala., where his death occurred.

Mr. Christie was a delightful companion, an exceptionally capable engineer, and a man of much executive ability. He was widely read not only in engineering but also in the literary Classics, particularly in the English essays. His range of knowledge was wide and accurate. It was a rare pleasure to spend an evening with him and listen to his descriptions of men and affairs. His humor was keen and his characterizations were accurate. The work he performed as Engineer and Contractor was well done.

He was married to Myrthé Baquié, on January 14, 1908. He is survived by his widow, two brothers, W. H. Christie and James Kent Christie, and a sister, Caroline Christie.

Mr. Christie was elected a Member of the American Society of Civil Engineers on October 2, 1895.

BERNARD LABROQUERE CROZIER, M. Am. Soc. C. E.[1]

Died July 23, 1938

Bernard Labroquere Crozier was born in Baltimore County, Maryland, on February 8, 1887. He attended the public schools in Baltimore, Md., including the Baltimore City College. In 1906, he completed the third year in the Alabama Polytechnic Institute, Auburn, Ala. Mr. Crozier received the degree of Bachelor of Laws from the Baltimore Law School in 1911, and was admitted to the Maryland State Bar in the same year. He attended the night classes at the Johns Hopkins University, Baltimore, in 1916, 1917, 1919, and 1920.

Mr. Crozier's first employment was with the Baltimore and Ohio Railroad Company, as Rodman, from March 7 to April 7, 1906. From September, 1906, to January, 1909, he served as Rodman and Instrumentman with the United Railways and Electric Company, of Baltimore; and, from August 12, 1909, to July 17, 1912, he was employed as an Inspector with the Maryland State Roads Commission.

Mr. Crozier was an Assistant Engineer with the Paving Commission of Baltimore, from July 18, 1912, to February 20, 1918, and, during the World War in 1918, he was Assistant Superintendent of Shops with the Bartlett-Hayward Company of Baltimore, which Company was engaged in making munitions of war.

When the Paving Commission of Baltimore resumed its paving program on February 17, 1919, he was appointed Office Engineer, and held that position until June 12, 1923, when he was appointed Highways Engineer of Baltimore. On July 1, 1925, when the Department of Public Works was created, he was promoted to the position of Chief Engineer. By virtue of this office, he was a member of the Board of Estimates and a member of the Public Improvement Commission of the City of Baltimore.

Due to a change in administration in Baltimore, on October 1, 1927, a new Chief Engineer was appointed, and Mr. Crozier then opened an office as Consulting Engineer. As such he designed and supervised the construction of several highway bridges for the City of Baltimore.

On April 11, 1929, he was appointed Chief Engineer of the Metropolitan District of Baltimore County, Maryland, which position he held until he was again, on June 15, 1931, appointed Chief Engineer of the Department of Public Works, which position he held at the time of his death. This Department embraces eleven bureaus, covering all the engineering work of the City, except that of the Park Board.

During Mr. Crozier's terms as Chief Engineer, many large public improvements were planned and constructed. He was highly esteemed as an efficient public servant, and his loss is deeply regretted by his many friends.

---

[1] Memoir prepared by Frank K. Duncan, M. Am. Soc. C. E.

On December 6, 1913, he was married to India J. Yewell, who, with a sister, Mrs. James Arthur, of Houston, Tex., survives him.

He was a member of the Engineers Club of Baltimore and President of the Maryland Association of Engineers at the time of his death. He was a York and Scottish Rite Mason and a Noble of the Mystic Shrine.

Mr. Crozier was elected an Associate Member of the American Society of Civil Engineers on January 19, 1920, and a Member on March 15, 1926.

EDGAR DUDLEY CRUISE, M. Am. Soc. C. E.[1]

Died June 5, 1938

Edgar Dudley Cruise was born on February 22, 1867, at Wyandotte (later Kansas City), Kans. He was educated in the Public Schools of that city and matriculated at the University of Kansas, at Lawrence, Kans., in September, 1883, at which time the writer's lifelong friendship with him began.

He left college in the Spring of 1887, after the completion of more than three years' work in the College of Engineering, and entered the service of the Missouri Pacific Railroad Company, expecting to return to the University for his final semester, but as promotion followed promotion, he never did receive his diploma.

He was employed steadily from May, 1887, until March, 1900. Rodman, Instrumentman, Resident Engineer, Engineer for Contractors on bridge construction, and several years of service for Armour and Company in various capacities, including the position of branch manager—these engagements constituted the various steps in his post-college training for his life work of location and construction.

From March, 1900, to March, 1909, he was on railroad location, continuously, for the Choctaw, Oklahoma and Gulf Railroad Company in Oklahoma, the Kansas City, Mexico and Orient Railway Company of Texas, and for nearly seven years of this period with the Southern Pacific Railroad Company in Arizona and Mexico. He was in full charge of location of the lines of the latter company in Mexico.

From March, 1909, to November, 1916, he was back on construction work as Division Engineer on the Kansas City, Mexico and Orient Railway in Texas. During this period he was also in charge of an irrigation project and dam in Southwest Texas, and served as construction engineer of the Teton Basin Branch of the Oregon Short Line Railway and of 70 miles of the Salt Lake and Utah Railway.

In November, 1916, Mr. Cruise became principal locating engineer of the Union Pacific Railroad Company with headquarters at Omaha, Nebr. He retained that position until November, 1918, when he turned from railway work to the location and construction of the rapidly developing highway system of the United States.

---

[1] Memoir prepared by Henry E. Riggs, Past-President, Am. Soc. C. E.

For four years he was Resident and District Engineer for the Tennessee Highway Department; then for three years he was Principal Locating Engineer for the North Carolina Highway Commission, after which he was called back to Mexico as Principal Locating Engineer and Chief Engineer for the Comision Nacional de Caminos. From October, 1925, to January, 1927, he was Principal Locating Engineer and Chief Engineer on construction of 600 miles of highway between Laredo, Tex., and Puebla, in Mexico, and for the next two years was engaged on highway studies in Central America.

On the completion of this work he returned to the United States and for about two years was at his boyhood home in Kansas City. In February, 1931, he entered the service of the New Mexico State Highway Department and was with that organization continuously for eight years until his death, caused by an automobile accident, on June 5, 1938.

The foregoing sketch of fifty busy years shows clearly the fact that his work was largely pioneering in new and partly developed areas, and that he was an out-of-doors man—literally, an " engineer at the front " during his entire life.

The writer's friendship with him extended over the more than half a century from his entrance in the freshman class of the University of Kansas and his joining Phi Gamma Delta Fraternity until his death.

Two months before Mr. Cruise's death, the writer attended a meeting of the New Mexico Section at Albuquerque. Edgar Cruise, Life Member, with his wife, drove 260 miles to the meeting, and he and the writer spent a most enjoyable half-day together. In 1936 it was the writer's privilege to spend a week in New Mexico and to go with him over his work then in progress. Charles M. Upham, his chief on the North Carolina work, has stated that " his work was always of outstanding quality."

Mr. Cruise was a man of few words, loyal to his friends, loyal to his employer and to the men under him, and faithful to the job, whatever or wherever it was. He made many good friends wherever he worked and was esteemed by all who knew him as an excellent engineer and a man of fine personality and high ideals.

He was married June 6, 1894, at Topeka, Kans., to Sarah Corinna Wharry. They had one son, John D. Cruise, M. Am. Soc. C. E., a graduate of the Engineering College of the University of Michigan, at Ann Arbor, Mich.

The writer will always carry the picture of Edgar Cruise as he was in April of 1938, a handsome, upstanding man whose outdoor life had given him the bronze of perfect health, and whose more than seventy years was indicated only by his snow-white hair; a man who still had the modesty and apparent shyness of the sixteen-year-old boy of years gone by, and with the same friendliness and hearty hand-clasp. That last picture of the dear old friend will never fade. It was his good fortune to be " in harness " until the final call came. In perfect health, and with joy in his work, he could look back on long years of splendid service in the task of making America a better place in which to live.

Mr. Cruise was elected a Member of the American Society of Civil Engineers on June 4, 1913.

BENJAMIN HERMAN DAVIS, M. Am. Soc. C. E.[1]

Died August 17, 1927

Benjamin Herman Davis, the son of Dr. Benjamin Byron Davis and Sophie (Shultz) Davis, was born in Palmyra, Ohio, on October 15, 1882. He received his early education in the public schools of Palmyra, and his engineering education at the Case School of Applied Science, at Cleveland, Ohio, which, in 1905, conferred upon him the degree of Bachelor of Science in Civil Engineering. He was a member of the Alpha Tau Omega Fraternity.

After his graduation Mr. Davis served for a short time as Laboratory Assistant in the Department of Testing Materials of the Osborn Engineering Company, at Cleveland. From September, 1905, to March, 1906, he was employed as Draftsman on the design and detail of steel and reinforced concrete structures in the Bridge Department of the Lake Shore and Michigan Southern Railway Company. In this latter position, he laid the groundwork for his future career.

In March, 1906, Mr. Davis left the employment of the Lake Shore and Michigan Southern Railway Company to become Engineer of Concrete Structures for the Delaware, Lackawanna and Western Railroad Company, at Hoboken, N. J., where he continued to serve until April, 1910, when he resigned his position to enter private practice. It was while employed by the Lackawanna Railroad Company that Mr. Davis became an enthusiast in the promotion, design, and construction of concrete structures. It was also at this point in his career that he made close friendships with Lincoln Bush, Past-President and Hon. M. Am. Soc. C. E., George T. Hand, M. Am. Soc. C. E., and others, who were to be of great assistance to him in his private practice as a Consulting Engineer in concrete construction. During Mr. Davis' employment with the Lackawanna Railroad Company he had charge of the construction of more than one hundred concrete bridges, the most important of which were the Paulin's Kill Viaduct, at Hainesburg, N. J., and the Delaware River Bridge, at Slateford, Pa.

From May, 1910, to the time of his death, Mr. Davis continued in private practice as a Consulting Engineer on the design and construction of all types of concrete structures. To enumerate all the structures with which he was connected during this period would require too much space. Therefore, only a few of the more important ones will be mentioned, such as the Penn Street Bridge over the Schuylkill River, at Reading, Pa., for Berks County, Pennsylvania; the Market Street Bridge over the Tennessee River, at Chattanooga, Tenn., for Hamilton County, Tennessee; Central Bridge over the Merrimac River and Essex County Canals, for the City of Lawrence, Mass.; Seventh Street Bridge over the James River, Norfolk and Western, Chesapeake and Ohio, and Southern Railroad tracks for the Norfolk Western Railway Company, at Lynchburg, Va.; the Washington Memorial Bridge over

---

[1] **Memoir prepared by George J. Ray and George L. Dresser, Members, Am. Soc. C. E.**

Brandywine River, at Wilmington, Del., for New Castle County, Delaware; the Great Western Gateway Bridge over the Mohawk River, at Schenectady, N. Y., for the State of New York; and the Market Street Bridge over the Susquehanna River, at Wilkes-Barre, Pa., for Luzerne County, Pennsylvania.

During the World War, Mr. Davis became interested in the design and construction of concrete ships for the United States Government. He devoted considerable time and energy toward the development of this type of carrier. After the war, he became interested in the design and erection of lofty, reinforced concrete memorials to World War heroes.

During his career, he also acted as Consulting Engineer and Designer in the construction of several trainsheds for railroad companies and as a Consulting Engineer and Designer of several reinforced concrete buildings.

Mr. Davis had a most pleasing personality. He possessed an enthusiasm and knowledge in the design and construction of concrete structures, which was infectious and inspired confidence, not only among his associates, but among all with whom he came in contact. He was a tremendous worker, and never during his career as a Consulting Engineer did he permit a design or specification to leave his office until he had checked it carefully, and made himself entirely familiar with every detail. To every job under Mr. Davis' supervision, whether large or small, he gave of his great enthusiasm and knowledge of detail. He had a rare combination of engineering ability and salesmanship. His technical opinions and designs were always sound, and his integrity was always above question.

On July 28, 1918, Mr. Davis was married to Mabel DeWees, at New York, N. Y., and to them were born the following children: Benjamin Herman, Marjorie Angela, Dorothy Jeanne, and Joanne Louise, who, with his widow and mother, survive him.

He was a member of the American Association of Engineers, the American Concrete Institute, the Albany Society of Engineers, the American Society for Testing Materials, and the Engineers Society of Pennsylvania.

Mr. Davis was elected an Associate Member of the American Society of Civil Engineers on November 30, 1909, and a Member on October 15, 1923.

RALPH GRAY DAVIS, M. Am. Soc. C. E.[1]

Died February 21, 1939

Ralph Gray Davis, the son of Alfred and Ada (Gray) Davis, was born in Elkton, Md., on July 23, 1888. He received his elementary education in the Elkton Public Schools and then entered the University of Delaware at Newark, Del., from which he was graduated in 1911 with the degree of Bachelor of Science in Civil Engineering. In 1930 he was awarded an honorary degree in Civil Engineering by the same university.

---

[1] Memoir prepared by Forrest E. Byrns, Assoc. M. Am. Soc. C. E.

Immediately after his graduation, Mr. Davis accepted a position as Recorder and Surveyman in the United States Engineer Office at Wilmington, Del. He was promoted to Inspector the following year and continued in that capacity until December 28, 1917, when he resigned to accept a commission as Second Lieutenant in the 57th Engineers, with which organization he served his country overseas from June 30, 1918 to July 30, 1919.

After his return from France, Mr. Davis again entered the Civil Service in the Wilmington Engineer District, with the grade of Junior Engineer. His principal work in the several years following was in connection with the reconstruction of the Chesapeake and Delaware Canal, a $10 500 000 project, for which he had charge of all surveys and later the design and preparation of construction drawings.

He was promoted to Assistant Engineer in 1926, to Associate Engineer in 1929, and to the grade of Engineer in 1930. At that time he was assigned as Principal Civilian Assistant to the District Engineer and placed in responsible charge of all engineering work in the Wilmington District.

In the River and Harbor Act of 1930, Congress provided for the organization of the Beach Erosion Board to make special studies throughout the various States and territories with a view to devising effective means of preventing shore erosion. It was the opinion of Earl I. Brown, M. Am. Soc. C. E., a recognized authority on the subject, that Mr. Davis' work on the Chesapeake and Delaware Canal and his interest in studies pertaining to its hydraulic characteristics and in studies relating to other coastal improvements, placed him foremost among those engineers available for duty with the Board.

Accordingly, Mr. Davis was prevailed upon to accept a position on the Board's staff, in the office of the Chief of Engineers, Washington, D. C. On July 6, 1931, he assumed duties as Senior Assistant to the Resident Member and was placed in charge of all field work of the Board and the preparation of its technical reports. In 1935 he was promoted to the grade of Senior Engineer. While on official duty, starting on an inspection trip in April, 1934, he suffered severe injuries in an automobile accident from which he never fully recovered and which ultimately caused his death.

Mr. Davis was a close student of tidal hydraulics and of shore processes and shore-line development. His experience and sound judgment on problems dealing with the protection and preservation of beaches were of inestimable value to the Beach Erosion Board. His quiet, unassuming manner and cheerful personality endeared him to all of his associates. His principal interest outside of his family and his work was in the science of photography which, to him, was a fine art as well as an absorbing hobby.

On January 26, 1916, Mr. Davis was married at Elkton to Margery E. Marshbank of that city. He is survived by his widow and their two children, Margery M., and Ralph Gray Davis, Jr., and a brother, A. Victor Davis.

He was a member of the Society of American Military Engineers, the American Legion, and several organizations of the Masonic Order, including St. John's Commandery No. 1, Knights Templar, of Wilmington, and the Boumi Temple Shrine.

Mr. Davis was elected a Member of the American Society of Civil Engineers on February 10, 1930.

JAMES HERVEY DINGLE, M. Am. Soc. C. E.[1]

Died June 3, 1938

James Hervey Dingle, the son of Gabriel Wesley Dingle and Josephine (von Siebold) Dingle, was born in Charleston, S. C., on September 9, 1869. He was educated in private schools and at the High School of that city; and, in 1888, he received the degree of Bachelor of Arts from the College of Charleston. Later, he entered Cornell University, at Ithaca, N. Y., from which he was graduated in 1892 with the degree of Civil Engineer.

After his graduation Mr. Dingle returned to Charleston, and, for six months, was engaged in the private practice of his profession. In January, 1893, he was made Assistant City Civil Engineer, which office he held until January 1, 1894, when the title of office was changed and he was made City Surveyor, which position he filled from 1894 to 1905, when the title of office was again changed to that of City Engineer. On January 1, 1905, he was elected City Engineer, which position he held until his death.

During the forty-five years that Mr. Dingle served the City of Charleston, he had charge of the repaving of the entire city, substituting modern paving for dirt, clay, oyster shells, and cobble-stones; the design and installation of a modern sanitary sewerage system; the enlargement of the storm-water drainage system; building of the Murray Boulevard and sea-wall; construction of a modern incinerator; and, more recently, the construction of an aviation field, and during 1937 the construction of a sea-plane base in anticipation of Trans-Atlantic Service. These engineering accomplishments will be lasting memorials to his efficiency, fidelity, engineering ability, and service to his fellow men and to the City.

Mr. Dingle's duties as Head of the Department of Public Service of the City of Charleston included the supervision, construction, improvement, and maintenance of all streets, and the supervision of garbage collection and disposal. He was also Engineer for the Zoning Administration.

With but one exception (a member of the Fire Department), Mr. Dingle, in point of service, was the oldest employee of the City of Charleston, and had the honor and distinction of having served continuously under seven Mayors of the city.

In addition to his professional work, Mr. Dingle found time to devote to many public interests. He was an officer in the Washington Light Infantry, rising to the rank of Captain. He was Past-Master of Pythagorean Lodge, A. F. M., and a Noble of Omar Temple, Imperial Council, A. A. O. N. of the M. S., for North America. He was a member of the Knights of Pythias, the German Friendly Society, the Alumni Association of the College of Charleston, the Cornell Association of Civil Engineers, and the American Society of Municipal Engineers. This latter Society, in 1931, awarded him its medal for continuous service with one employer—45 yr with the Municipal Government of Charleston. He was also a member of the Public Works Association, and the American Society for Testing Materials. He was one of the Charter Members of the South Carolina Society of Engineers, and the South Carolina Section of the American Society of Civil Engineers, and was Past-President of both these organizations.

---

[1] Memoir prepared by a Committee of the South Carolina Section, consisting of J. E. Gibson and L. S. LeTellier, Members, Am. Soc. C. E.

He was a member of St. John's Lutheran Church and served as a member of its Board of Vestry and Wardens from 1894 to 1898, and again from 1917 to his death. In 1931, he was made President of the Congregation, which office he held at the time of his death. A resolution passed by the Board of Vestry and Wardens and the Congregation upon his death, reads as follows:

> "Mr. Dingle, by his Christian faith and fine devotion; by his gentlemanly culture and tactful courtesy; by his clear interpretation of parliamentary law; by his keen appreciation of the splendid traditions of St. John's Church; and by his impartial decisions at our Board and Congregational meetings, made justice and good will to prevail, and the memory of our personal and official association with him shall long be cherished as one of life's choicest privileges."

Mr. Dingle also served on The Board of Education of The United Lutheran Church in America from 1926 to 1932.

In 1899, he was married to Olive Bartlett Olney of Charleston, who, with one daughter, Josephine von Siebold Dingle, and a sister, Mrs. John Rutledge Dingle, survives him. His only son, James H. Dingle, Jr., died in early youth.

Mr. Dingle was elected a Junior of the American Society of Civil Engineers on April 30, 1895; an Associate Member on October 4, 1899; and a Member on November 28, 1916. He became a Life Member on January 1 1934.

VICTOR GELINEAU, M. Am. Soc. C. E.[1]

DIED JANUARY 21, 1938

Victor Gelineau was born in Lowell, Mass., on January 21, 1886, the son of Cesaire and Mary (Lemieux) Gelineau. His technical training was obtained in the College of Civil Engineering at Cornell University, Ithaca, N. Y. He also held a Law degree which he received in 1922 from New York University, at New York, N. Y.

Mr. Gelineau began the active practice of engineering at Atlantic City, N. J., as Draftsman, Transitman, and Computer on general surveying and municipal work; then, shortly thereafter, as First Assistant in charge of all field work and design for the municipal work of Hammonton, Egg Harbor City, and South Atlantic City, in New Jersey, including drainage systems, roads, pavements, bulkheads, bridges, and ocean-front board walks; hydraulic dredging and land reclamation; and water power and water supply surveys. His work also included surveys and the sub-division of large tracts of land; water power, and water supply surveys; plans and estimates for Mays Landing (N. J.) Power Company, and plans for a channel and bridge connecting Atlantic City and Brigantine Beach, in New Jersey. By this early experience in work on the South Jersey waterways, he developed a keen interest in the waterway and coastal problems and the possibilities for the development of these areas of the State for recreational and residential uses.

---

[1] Memoir prepared by a Committee consisting of Charles W. Staniford, M. Am. Soc. C. E., *Chairman*, J. Spencer Smith, Pres., Board of Commerce and Nav., State of New Jersey, Tenafly, N. J., and Robert Simon, Office Engr., Board of Commerce and Nav., State of New Jersey, Newark, N. J.

In 1910 and 1911, Mr. Gelineau was Assistant Chief Engineer in charge of field work and design of sub-division, road location and construction, surveys, and designs for bridges, and bulkheads and board walks, for an extensive land development at Tangier, Long Island, N. Y.

In 1912, he entered the service of the State of New Jersey, in the Department of Inland Waterways, as Draftsman, Computer, and Field Assistant on topographic and hydrographic surveys, hydraulic channel dredging work in connection with the construction of the Inland Waterway Channel extending along the New Jersey coast from Cape May to Bay Head, and the construction of the Barnegat Bay-Manasquan River Canal.

From 1916 to 1918 he was engaged on surveys for the proposed New Jersey Ship Canal from Delaware River to Raritan Canal and in charge of surveys and investigations of unauthorized occupations of the State's lands under water for the Board of Commerce and Navigation of New Jersey.

Mr. Gelineau was appointed Acting Director of the Board of Commerce and Navigation in May, 1918, and Director and Chief Engineer in November, 1918, which office he held until the time of his death.

As Chief Administrator of the Board he devoted his talents and ability to the best interests of the State, and gave conscientious service to the public which won for him the undeniable respect of all those with whom he came in contact. He had an abiding interest in his work and pursued the details of the many functions of the Board from both the engineering and legal standpoints. As Director of the Board, Mr. Gelineau prepared many of its reports, notably the several reports on the erosion and protection of the New Jersey beaches and the preliminary report on the reclamation of the Hackensack (New Jersey) Meadows.

He made a thorough study of riparian law and its application. He was regarded as an expert in this complex and specialized subject, and his counsel on riparian questions was sought and accepted by engineers engaged on waterfront structures, and leading legal authorities. He was the author of the monograph, "Riparian Rights—Certain Principles of the Law and Its Application."

Perhaps his outstanding contribution to his profession is his work on, and study of, beach erosion and protection. In this field he was considered the ranking expert in the United States, if not in the world. Under his leadership, the State of New Jersey was the first State to recognize the need for a comprehensive plan for beach protection to be undertaken by the community and the State, rather than the individual shore owners. His designs of sea walls, jetties, groins, and bulkheads, have withstood the test of time and ravages of the sea, and have proved their effectiveness in stabilizing and building up the beach. He devised the successful methods for preventing the erosion that had threatened the destruction of Barnegat Light.

In 1930, Mr. Gelineau was appointed one of the three civilian members of the United States Beach Erosion Board. As a member of this Board, he inspected and familiarized himself with the problems of shore protection along the entire Atlantic and Pacific seaboards. He was consultant on beach protection projects in Florida and in Long Island, New York.

Mr. Gelineau made frequent trips to Washington, D. C., representing the State of New Jersey, to urge the improvement of its waterways. He had attended the Thirty-Third Annual Convention of the National Rivers and Harbors Congress, at Washington, and was returning home when sudden death, on his fifty-second birthway, cut short a remarkable career.

Mr. Gelineau was Secretary and Treasurer of the American Shore and Beach Preservation Association, a member of the National Society of Professional Engineers, New Jersey State League of Municipalities, American Planning and Civic Association, The Canadian Society of New York, Cornell Club of New York, and the American Power Boat Association. He was a Past-Secretary of the American Association of Port Authorities and a Past-President of the Society of Terminal Engineers. On January 15, 1938, he was inducted into office as President of the New Jersey Association of Professional Engineers and Land Surveyors. He was also a member of the Masonic Order.

Victor Gelineau was fully conscious of the obligation of citizenship, and participated in community and State activities. He was liberal in his thinking and the giving of his time for worthy causes. He believed sincerely that public office was a public trust, and acted accordingly. That he carried into his daily life his beliefs is attested by the unusually large number of tributes paid to his memory by those who came in contact with him, whether officials in high places, governing bodies, or individuals. A great public servant and a real gentleman has passed on.

The following is a resolution adopted by the Metropolitan Section of the American Society of Civil Engineers:

> "*Whereas,* the late Victor Gelineau was for many years an active member of the Metropolitan Section of the American Society of Civil Engineers and at the time of his death was a valued member of its Board of Directors, be it
>
> "*Resolved,* that the Board of Directors of the Metropolitan Section, American Society of Civil Engineers, hereby expresses its deep sorrow at the loss of so eminent a member, and be it
>
> "*Further Resolved,* that these resolutions be entered in the minutes of the Board and a copy thereof transmitted to Mrs. Gelineau, with the heartfelt sympathy of his former associates."

A memorial service was held on April 19, 1938, in the auditorium of the Department of the Interior Building, in Washington, D. C., in memory of the several Directors of the American Shore and Beach Preservation Association who had died. Richard K. Hale, Assoc. M. Am. Soc. C. E., of Massachusetts, paid a glowing tribute to the achievements of Victor Gelineau. Arthur S. Tuttle, Past-President, Am. Soc. C. E., presided. Captain Robert

W. Workman, Chaplain, U. S. Navy, offered the Invocation and pronounced the Benediction.

Many resolutions were adopted on the death of Mr. Gelineau by various Government, State, city and civic bodies, including the following: U. S. Beach Erosion Board, National Rivers and Harbors Congress, Harbor Control Board of Atlantic Highlands, N. J., New Jersey State Board of Commerce and Navigation, New Jersey Association of Professional Engineers and Land Surveyors, Society of Terminal Engineers, City of North Wildwood, N. J., South Jersey Port Commission, and American Shore and Beach Preservation Association; and many personal expressions of sympathy were received from various parts of the United States.

Mr. Gelineau wrote numerous reports and technical papers relating to coast protection problems and the waterways of New Jersey, among which are the following: "Particulars of the Administrative Powers and Functions of the New Jersey Board of Commerce and Navigation"; "Hudson's Matchless Waterfront and the State's Great Waterways"; "Port Planning and Improvement—Certain Engineering and Legal Considerations"; "Coast Protection with Related Principles"; "Recent Construction and Improvement of Activities on the New Jersey Waterfront"; "Coast Protection and the Public Interest"; "Save the Band of Golden Beaches"; "Economics of the Coast"; "Barnegat Lighthouse"; "The Work of the United States Beach Erosion Board and Study of Erosion"; "Principles and Present Practice of Sandy Seacoast Protection"; "New Jersey Coast Protection Problems"; "Surveys on the Coast of New Jersey"[2]; "Coast Protection Problems in the Metropolitan Regions"; "The Accomplishment of Beach Preservation in New Jersey"; "Hampton Problems" (Hampton Beach, N. H.); "State's Interest in the Preservation and Improvement of Sea Beaches"; "Report on Reclamation of the Meadows and Improvement of Adjacent Waterways within the New Jersey Portion of the Port of New York"; "Damage to New Jersey Coast Resulting from the Storm of 1932"; and, "Special Report of New Jersey State Board of Commerce and Navigation to Governor and Legislature of New Jersey * * * Summary of Riparian Rights, Power Vessels on Inland Lakes, Inland Waterways, New Jersey Ship Canal, Delaware and Raritan Canal Abandonment, Coast Protection, Public Parks."

Mr. Gelineau was elected a Member of the American Society of Civil Engineers on September 10, 1923.

WILLIAM TILLOTSON GOULD, M. Am. Soc. C. E.[1]

DIED FEBRUARY 11, 1939

William Tillotson Gould was born at Paducah, Ky., on December 5, 1858, the son of Captain John Vinson Gould, Civil Engineer (born at Stonington,

---

[2] *Transactions*, Am. Soc. C. E., Vol. 92 (1928), p. 1501.

[1] Memoir prepared by W. H. Kirkbride, M. Am. Soc. C. E.

Conn.), and Mira Rebecca (Bronson) Gould, of Woodford County, Kentucky. William Gould was graduated from the High School at Paducah in June, 1876, having also studied under his father in the field and in the office from 1872 to 1876.

For four years immediately after graduation, he served as City Engineer for Paducah, engaged on engineering surveys, construction, and drainage work. During this period he furthered his education by self study.

From 1880 to 1885 he was engaged in various engineering capacities from Leveler to Resident Engineer for the Northern Pacific Railroad Company, on railroad location and construction work on various parts of the system.

From June, 1886, to April, 1902, he was engaged, principally as Resident Engineer, on location, construction, and maintenance, by several railroad companies in the Central and Southern States. For eight months of this period he was employed by the Northern Pacific Railroad Company as Resident Engineer on the construction of a branch railroad in the Cascade Mountains in Washington.

From April, 1902, to June, 1904, Mr. Gould was engaged as Assistant Engineer with the Brooklyn Rapid Transit Company in connection with surveys, plans, and estimates for elevated railroad and tunnel connections on the East River Bridge and under the East River, the elimination of grade-crossings on the Brighton Beach Railroad, and special work on surface lines in Brooklyn, N. Y.

From July, 1904, to April, 1911, he was engaged as Assistant Engineer by the Pennsylvania Railroad Company in connection with the construction of railroad terminals at New York, N. Y., and environs. From that time until June, 1913, he served as Expert Aide with the United States Navy in connection with the construction of Dry Dock No. 4, New York Navy Yard, until its completion; thereafter he was in charge of the erection of large fuel oil, gasoline, and water station facilities at the United States Naval Station at Guantanamo, Cuba. The next three years he was Chief Engineer, and also Director, of the Nevada-California-Oregon Railway Company.

In May, 1917, Mr. Gould entered as a student at the United States Training Camps at Madison Barracks, New York, and on June 28, 1917, he was commissioned Captain, U. S. Army, Engineer Officers Reserve Corps. He went overseas in November, 1917, with the American Expeditionary Forces, and was in charge of the erection of large steel gasoline storage tanks, handling and distributing plants at Blaye, Furt, and St. Loubes, France.

Mr. Gould returned to America early in 1919 and in April resumed his former position as Chief Engineer of the Nevada-California-Oregon Railway —which railway later was made a part of the Southern Pacific Lines—and on March 31, 1930, having reached the age limit, he was retired and pensioned by the latter company.

Mr. Gould had a high sense of responsibility and devotion to duty and all work entrusted to him was completed with painstaking care. He was a skillful and accomplished engineer and a man of high principles and integrity.

He was a member of The Society of American Military Engineers, Companion: Military Order of the World War (life member). He was also an active member of the American Legion; and of the Engineers' Club, of St. Louis, Mo. (life member).

Mr. Gould died on February 11, 1939, at Hastings-on-Hudson, N. Y. He is survived by his widow, Mrs. Malvina Sassarans Gould, to whom he was married on January 1, 1895; and by a son, Mr. William T. Gould, Jr.; and a daughter, Mrs. E. F. Howrey.

Mr. Gould was elected a Member of the American Society of Civil Engineers on January 2, 1890.

AMBROSE GOULET GRANDPRÉ, M. Am. Soc. C. E.[1]

Died April 24, 1938

Ambrose Goulet Grandpré was born on July 31, 1883, at Kankakee, Ill., the son of Victor and Ida (Goulet) Grandpré. His father was born in Canada but grew up in Bourbonnais, Ill. The family later moved to Chicago, Ill., and Ambrose attended the Public and High Schools there and was graduated from West Division High School. He attended the University of Illinois, at Urbana, Ill., and was graduated in 1906 with the degree of Bachelor of Science in Civil Engineering.

After his graduation he was employed by the Chicago, Milwaukee and St. Paul Railroad Company in Montana and Washington. In 1909 he entered the employ of Marshall and Fox, Architects, in Chicago, as a Superintendent of construction. In this capacity he supervised construction of the Blackstone Hotel, Morrison Hotel, Chicago Burlington and Quincy Railroad Company Office Building, Federal Life Insurance Company Building, Woods Theater and Office Building, Lyon and Healy Building, and others.

In 1917 he became Construction Engineer for Longacre Engineering and Construction Company, in which capacity he had charge of construction of State-Lake, Apollo, Selwyn-Harris Theaters, Trianon Ball Room in Chicago, and Capital Theater in Detroit, Mich.

In 1923 he became a Vice-President of the firm of Bierd, Lydon and Grandpré, and in 1926 he was made President of the company. The company specialized in railway and industrial construction.

Some of the representative work done by this company under Mr. Grandpré's direction consisted of a foundry for Pettibone-Mulliken Company, at Chicago; a Terminal for the Missouri, Kansas and Texas Railroad Company at Denison, Tex.; Roundhouse for the Nickle Plate Railroad Company at Frankfort, Ind.; Roundhouse and Freight Terminal, at Battle Creek, Mich.; Sewage Disposal Plant, at Springfield, Ill., and Elyria, Ohio; Water Filtration Plant at Kenilworth, Ill.; and the Arlington Hotel at Binghamton, N. Y.

The Bierd, Lydon and Grandpré Company ceased operation in 1930, and in 1933 Mr. Grandpré went into business for himself, specializing in the installation of pipe work on dams, sewage and filtration plants, and power houses. He continued in this work until his death on April 24, 1938.

---

[1] Memoir prepared by Meyer Fridstein, M. Am. Soc. C. E.

He was married in Tekoa, Wash., on April 14, 1909, to Eleanor Harris who, with three children, Lorraine, Anonarose, and Ambrose Robert, survives him.

Mr. Grandpré was elected an Associate Member of the American Society of Civil Engineers on December 3, 1912, and a Member on January 19, 1925.

JOHN HENRY GRAY, M. Am. Soc. C. E.[1]

Died August 5, 1938

John Henry Gray, the son of James and Cordelia (Lyons) Gray, was born on May 26, 1865, at Watkins Glen, N. Y. His father was born in Scotland, and his mother was of Dutch descent. He attended the Cook Academy at Montour Falls, N. Y., and in 1883 he entered the Rensselaer Polytechnic Institute at Troy, N. Y., and was graduated in June, 1887, with the degree of Civil Engineer.

After graduation Mr. Gray served, for a time, with a firm of consulting engineers on sewage disposal plants and water works. In November, 1887, he entered the services of G. W. G. Ferris and Company of Pittsburgh, Pa., designing and inspecting steel for bridges and buildings. He continued in this type of work for the remainder of his professional life. In 1890 he was First Assistant Engineer for the Ferris Company. At the end of that year he was engaged by E. Duque Estrada and Edward H. Kenyon to form the engineering firm of Estrada, Kenyon and Gray with offices in Chicago, Ill., Pittsburgh, and Philadelphia, Pa.

It was at this time that he patented the building column which bears his name. It is an open section that can be painted inside and outside. The design results in economy of material, and is such that pipes and conduits can readily be installed within its area. It was used in a number of large buildings at that time, although it has since been almost completely displaced by other sections.

From 1893 to 1895 Mr. Gray was engaged in consulting practice in Chicago, designing, making shop drawings for, and inspecting, steel work of various framed structures. He designed two conveyor bridges of novel design for the Chicago Drainage Canal, with spans of 180 and 210 ft. They traveled in a direction transverse to their length and carried dump cars for excavated material, running longitudinally. Material was dug from the canal section with steam shovels, loaded on to the cars and dumped beneath the bridges when the car had been properly "spotted." When one allotted space had been filled the bridge was moved transversely and the operation repeated. This is probably one of the earliest cases of material being conveyed in large quantities, in this manner. After the excavation work was completed the towers were removed and the bridges were used as highway spans. Mr. Gray also designed an ornamental 140-ft arch highway span for Cyrus H. McCormick at Lake

---

[1] Memoir prepared by Thomas Earle, M. Am. Soc. C. E.

Forest, Ill. Such structures were unusual at that time and aroused considerable interest.

Mr. Gray was connected with the engineering firm of Davis and Sax of Philadelphia from 1895 to 1899, and was a member of the firm of Gray and Groneau of New York, N. Y., during some of that time.

In 1899, with Charles H. Davis and P. M. Sax, he formed the engineering firm of Gray, Davis and Sax in Philadelphia. This firm was dissolved in 1906 and Mr. Gray then formed the firm of J. H. Gray and Company in New York City. The latter firm was engaged primarily in general engineering practice until 1913, when it entered the contracting field. In 1918 Mr. Gray's health began to fail and he was forced to retire gradually from active work; his firm was dissolved in 1920.

Mr. Gray was particularly interested in the various engineering problems that arose in connection with the design and erection of steel structures.

From 1915 to 1917 he was Contractor's Engineer in connection with the replacement of the existing highway crossing over the Hudson River, at Troy, parallel to an older bridge. The old bridge consisted of a swing span and several approach spans. The swing spans in each structure were opposite each other. Traffic had to be maintained at all times over the old bridge and in the river. The bridges were so close to each other that the swing span in neither structure could be opened fully while both of them were in position. A temporary lift span was used to permit the passage of both river and highway traffic. Another serious difficulty arose from the fact that the center pier of the old span was immediately adjacent to the pivot pier of the new span; and the new foundation went down to rock whereas the pivot pier of the old span was built on piles, its base being about 20 ft higher than the base of the new pier. Therefore, there was great danger that excavating so low for the new span would undermine the old foundation. Mr. Gray solved this problem in a most satisfactory manner, and under unusual circumstances. A flood occurred in the Hudson River while work was in progress, at a season when the river stage is usually quite low.

Mr. Gray had wide experience in his field of work and was both ingenious and capable. He was an employer of many engineers and his loss has been felt widely.

On May 16, 1892, he was married to Thena G. Kirk, who survives him.

Mr. Gray was elected a Member of the American Society of Civil Engineers on October 2, 1895, becoming a life member in 1930.

JOHN HOWELL GRIFFITH, M. Am. Soc. C. E.[1]

Died July 14, 1938

John Howell Griffith was born in Detroit, Mich., on June 16, 1868. His parents were John Howell and Helen (Bristol) Griffith. He was the first born and only survivor of that union.

---

[1] Memoir prepared by A. H. Fuller, M. Am. Soc. C. E., and W. M. Dunagan, Esq., Ames, Iowa.

Mr. Griffith was graduated from the Department of Civil Engineering at the University of Wisconsin, in Madison, Wis., in 1893. He received the degree of Master of Science in Mathematics from the same institution in 1898. Throughout his career he alternated between teaching and engineering practice with an increasing interest in certain unsolved problems; research leading to the solution of these problems occupied the full time of his later years.

Mr. Griffith worked for railroads for three summers before graduation, and then had short-time engagements with the Brown Ketchum Iron Works, Gillett Hertzog Iron Works, Pittsburgh Bridge Company, Union Bridge Company, American Bridge Company, the Canadian Bridge Company, the Canadian Pacific Railway Company, and the Chicago and Northwestern Railway Company; he also did designing and estimating for William G. Fargo, M. Am. Soc. C. E., and was Designing Engineer under J. C. Bland, M. Am. Soc. C. E., of the Pennsylvania Railroad Company. He was Chief Draftsman for the James Stewart Contracting Company, Chief Draftsman for the American Structural Steel Company, and Chief Engineer for the Metallurgical Company of America. In 1893 he began an extended experience in structures with the Massillon Bridge Company where his most important work was on the Toledo Court House. In 1901 he was Assistant Engineer for the Cambria Steel Company with responsibility for the design of many buildings, bridges, and industrial plants. Mr. Ralph V. Sage, formerly of the Cambria Steel Company, states, "I respected and admired Mr. Griffith for his engineering knowledge and his desire to take responsibility. I also value highly his loyalty and friendship. His resignation was accepted with regrets by all of us."

His teaching experience began with the acceptance of a fellowship at the University of Wisconsin in 1897—first fellowship award in engineering of that University. After a year of graduate work, he was called to the Clarkson College of Technology at Potsdam, N. Y., where he organized a course in civil engineering and installed a hydraulic laboratory. He then returned to engineering work but was lured back into teaching by the University of Michigan at Ann Arbor, Mich., in 1907. Dean Mortimer Elwyn Cooley, Hon. M. Am. Soc. C. E., writes,

> "I liked Professor Griffith very much indeed. My own recollections are that he was a gentle-man, most considerate of others, thorough in teaching a subject rather difficult for students and one requiring much patience. The fact that his students respected him and did well is a fine testimonial. He taught applied mechanics and our late Professor Ziwet, with whom he was associated, frequently spoke of him in most complimentary terms. He was highly esteemed by all his colleagues. Would we could have more men of Professor Griffith's type in this world of ours which today is so upset and going we know not where."

A noteworthy epoch in his professional career started in 1911 when he began work for the U. S. Bureau of Standards. As engineer in charge of physical tests and equipment, he planned and superintended the construction of the physical testing laboratory at Pittsburgh, Pa. The outstanding piece of equipment here was the 10 000 000-lb testing machine built for the purpose of securing more reliable information concerning the behavior of large columns following the Quebec bridge failure. Bureau of Standards *Technologic Paper No. 101* reports his tests of eighteen large bridge columns; it is recognized as an outstanding contribution to the understanding of the behavior of heavy structural compression members. Researches in brick, terra cotta, and concrete columns of large dimensions served as the bases for other bulletins, each of which is noteworthy in its field. Mr. Griffith was also author of Bureau of Standards *Technologic Paper No. 121* on Strength and Other Properties of Wire Rope.

Mr. Griffith was unyielding in his reverence for the majesty of truth and virtue. He was a thorough scholar, a student of engineering and of Emerson and the philosophers. His private papers include many computations, results of investigations, and written discussions. He has submitted for publication only those which satisfied him. His "Theory of Secondary Stresses in Trusses"[2] was among the early publications in the United States on the subject. It was possibly the first one in which the principle of area moments was used as a basis for the computation of secondary stresses.

In 1919, Mr. Griffith responded to a call from Iowa State College at Ames, Iowa, as Professor of Experimental Engineering. For many years he carried a full schedule of teaching in the field of engineering materials. In 1934 he was transferred to full time as Research Engineer with the Engineering Experiment Station. At Iowa State College he was author of several bulletins for the Engineering Experiment Station: No. 101, Physical Properties of Earths, 1931; No. 117, Dynamics of Earth and other Macroscopic Matter; No. 128, Thermal Expansion of Typical Rocks, 1936; and, No. 131, Physical Properties of Typical American Rocks, 1937.

In Bulletin No. 117, Professor Griffith discusses and uses his formula[3] for intensity of the vertical pressure produced in earth masses by concentrated loads on the surface:

$$Z_z = -\frac{(n-2)}{2\pi} P \frac{\cos^n\theta}{Z^2}$$

In a letter to Mr. Griffith, Dr. Otto Karl Fröhlich says, "It was of special interest to me to learn that this equation was established by you as far back as 1929, because I considered my formula as new when I found it in 1931."

His research interest and aptitudes were evident in each employment; structures detailed under his supervision frequently contained innovations and some of his methods of computations, although not in formal publications, will long remain the property of his students and his colleagues. Mr. Griffith has contributed many articles to the engineering press on various subjects, including clays, soils, soil mechanics, foundations, cement, reinforced concrete, and structural theory. His writings reflect a comprehensive grasp of mechanics, mathematics, physics, chemistry, and geology, and their relation to engineering theory and practice. His works, like the works of many eminent scientists, are replete with a philosophy of unity which does not exclude even the poets from the family of builders.

---

[2] *Michigan Technic,* February, 1909.

[3] *Bulletin No. 117,* Iowa State College Eng. Experiment Station, Ames, Iowa, p. 56, Equation 45.

Mr. Griffith was married on April 17, 1895, to Ida Catherine Dengler of Madison. He is survived by one daughter, Mrs. Louis Stewart Louvan.

Mr. Griffith was elected an Associate Member of the American Society of Civil Engineers on April 3, 1907, and a Member on June 4, 1913.

EDWIN LINCOLN GRIMES, M. Am. Soc. C. E.[1]

Died March 4, 1939

Edwin Lincoln Grimes was born at Hubbardston, Mass., on November 8, 1864, the son of Edwin Grimes and Hannah Elizabeth (Ferguson) Grimes. He was the second of four sons. One of his brothers, Maurice W. Grimes, is a Member of the Society. Edwin received his early education in the common schools at Princeton, Mass., and later entered Worcester Polytechnic Institute, at Worcester, Mass., from which institution he was graduated with honors in 1887 with the degree of Bachelor of Science.

Following his graduation Mr. Grimes entered the employ of the Chicago, California and Santa Fe Railroad Company in Chicago, Ill., as a Draftsman. In February, 1888, he returned to Worcester, where he held the position of Assistant Engineer with Woods and Rugg, Consulting Engineers of that city. During this engagement he supervised the construction of the laboratory at Clark University in Worcester.

From May, 1889, to March, 1899, Mr. Grimes was associated with Chappell and Burke, Chappell and Smith and Thomas F. Chappell, of Rutland, Vt., as Assistant Engineer. During this engagement he was in charge of the re-survey of 66 miles of the Rutland Railroad, construction of 6 miles of the Bristol Railroad, and construction of the Ausable Branch of the Delaware and Hudson Canal Company Railroad (later the Delaware and Hudson Railroad Corporation). He also designed and supervised the construction of a 110 000-gal storage reservoir for Rochester, Vt., and the water supply for the J. and J. Rogers Company's pulp mill at Ausable Forks, N. Y.

In March, 1899, Mr. Grimes opened a consulting engineering office in his own name at Rutland, and maintained this office until August, 1902. In this capacity he was retained on a number of important and interesting projects, chief of which were the design and supervision of construction of the Boardman Memorial Arch Bridge, a 46-ft masonry span, at Pittsford, Vt.; the design and supervision of construction of a 150 000-gal, covered, storage reservoir at Pittsford; the design and supervision of construction of a 500-hp water-power development (consisting of a masonry dam, wooden penstock, and power-house), at Blackbrook, N. Y., for the J. and J. Rogers Company; preliminary and location surveys for the Whitehall and Granville Electric

---

[1] Memoir prepared by Donald Mills, Assoc. M. Am. Soc. C. E.

Railroad Company, about 25 miles in length; remeasuring quantities of the Rutland Canadian Railroad for valuation purposes; and designing the sewerage system for a part of the Village of Pittsford.

In August, 1902, Mr. Grimes closed his consulting engineering office and assumed the position of Principal Assistant Engineer, Bureau of Water Supply, Troy, N. Y. In September, 1903, he was promoted to Chief Engineer, in which capacity he was in charge of the completion of the additional water supply for the city, a project which ultimately cost $1 500 000. In January, 1908, he became City Engineer of Troy, and held this position until January, 1913, when he again opened his consulting engineering office in Troy. He maintained this office until April, 1919, when he moved to Atlanta, Ga., to become designing engineer for the J. B. McCrary Engineering Corporation of that city.

Mr. Grimes was employed by this company continuously for the remainder of his life. In the capacity of Designing Engineer he was responsible for the design of a large number of municipal water-works and sewerage systems, one of the most noteworthy of which was the Utoy Creek Disposal Plant, one of the units of the Atlanta Metropolitan Sewerage System. At the time of his death Mr. Grimes was in charge of the construction of a $500 000 gravity water-supply project for Washington County, Virginia.

In 1937 he was presented with a gold plaque commemorating the golden anniversary of his graduation from Worcester Polytechnic Institute. In November, 1937, he received his certificate of life membership from the American Society of Civil Engineers. Mr. Grimes was also an active member of the American Waterworks Association and of the New England Waterworks Association.

He was held in high esteem by his many friends, both in the profession and in private life, and his kindly and lovable manner made a lasting impression upon all with whom he came in contact. His entire life was devoted to the civil engineering profession, and his engineering contributions to the well being of mankind constitute his greatest epitaph.

Mr. Grimes was married to Elizabeth Shangrau of Pittsford on March 10, 1892. His wife preceded him in death on December 1, 1926.

Mr. Grimes was elected a Member of the American Society of Civil Engineers on March 2, 1904.

CARL EWALD GRUNSKY, JR., M. Am. Soc. C. E.[1]

Died March 22, 1938

Carl Ewald Grunsky, Jr., added luster to a famous engineering name. Son of the late Carl Ewald Grunsky, Past-President, Am. Soc. C. E., and Martha (Powers) Grunsky, he was born at Sacramento, Calif., on December 12, 1884. After progressing through the public schools and the Polytechnic

---

[1] Memoir prepared by Frank E. Bonner, M. Am. Soc. C. E.

High School, of San Francisco, Calif., he took up his technical education at the University of California, at Berkeley, Calif., from which he was graduated in 1905 with the degree of Bachelor of Science in Mining Engineering. He then went on with his engineering training at Columbia University, at New York, N. Y., where he obtained the degree of Engineer of Mines in 1907.

Through the following ten years Mr. Grunsky's work was mostly in the mining field. He started with the Bunker Hill and Sullivan Mine in Northern Idaho and then went to South America for a year, where he served as Resident Engineer with the Rinconada Mining Company, at Poto, Peru. Returning to the United States at the beginning of 1910, Mr. Grunsky was engaged for several months as Engineer and Mill Foreman by the United Colorado Mines Company at Dorchester, Colo., and, afterward, for two years as Assistant Engineer by the American Engineering Corporation of San Francisco. In June, 1912, he assumed the position of General Superintendent for the Standard Consolidated Mining Company at Bodie, Calif. About a year later he rejoined the staff of the American Engineering Corporation with which he continued as Consulting Engineer for the Standard Consolidated Mining Company and, at the same time, specialized in mine examinations and valuations of many other properties.

Soon after the entrance of the United States into the World War in 1917, Mr. Grunsky was commissioned as Captain in the Engineer Corps of the United States Army. His first assignment was on the construction and operation of Camp Kearney, at San Diego, Calif. He went overseas in July, 1918, and served as Personnel Adjutant on the Staff of Brig.-Gen. (then Colonel) G. B. Pillsbury, Corps of Engineers, U. S. Army (*Retired*), M. Am. Soc. C. E., 115th Engineers. During January and February, 1919, Captain Grunsky was assigned to detached service with the Engineering Department, of the United States Peace Commission, at Paris, France, on the assessment of damages done in France. At the conclusion of his military service in July, 1919, Mr. Grunsky joined his father as a partner in the consulting engineering firm of C. E. Grunsky Company, at San Francisco. During the succeeding five years, he was engaged on many projects involving the design and construction of highways, irrigation, and water supply works, and in the valuation of gas, water, and electric utilities.

Upon the organization of the East Bay Municipal Utility District, in 1924, which had for its purpose the development of the Mokelumne River water supply for Oakland, Berkeley, and the seven other California cities along the east shore of San Francisco Bay, Mr. Grunsky was selected by the Chief Engineer, the late Arthur Powell Davis, Past-President, Am. Soc. C. E., to be Resident Engineer on the construction of Pardee Dam. Under Mr. Grunsky's capable supervision the construction operations on this great structure, which rises 360 ft above the foundations and impounds 222 000 acre-ft of water, were accomplished with complete success. When the Mokelumne Project was finished and the District assumed operation of the water service in the East Bay cities, Mr. Grunsky was appointed General Superintendent for the District and placed in charge of the operation and maintenance of the Mokelumne System. He continued in this position until his death.

Diversion of a large part of the Mokelumne flow to the distant seacoast cities inevitably led to serious litigation over water rights between the District and the water users along the river. Complicated technical questions arose concerning the relation of the river discharge to adjacent ground-water supplies. Mr. Grunsky directed the comprehensive engineering investigations and studies conducted by the District throughout the entire 8-yr period, and it was largely due to his diligence, clear judgment, and passion for fair dealing that a successful compromise of the controverted issues was finally achieved just two months before his death. This settlement confirmed the rights of the District to conserve and divert enough water ultimately for the needs of 2 000 000 population. In all the varied history of water-right litigation in California, no engineer had attained a more conspicuous success in arbitrating an important water controversy. The ample water supply now assured to support future expansion of the East Bay cities will stand as an enduring monument to his memory.

Mr. Grunsky's sudden passing after a major operation, while in the prime of life and accomplishment, was a shock to his host of friends and co-workers. His exceptional professional attainments, outstanding integrity, and conscientious application to his work, commanded the respect of his fellow engineers; and the intense loyalty of his subordinates offers ample evidence of his friendly, human qualities.

The high esteem in which Mr. Grunsky was held by his employers is well expressed in the following resolution adopted by the Board of Directors of the East Bay Municipal Utility District on March 23, 1938:

> "On March twenty-second, nineteen hundred and thirty-eight, Carl Ewald Grunsky, Jr., was called to his final rest. His place in his profession was high, his record of accomplishment great. One of the pioneer professional men with the East Bay Municipal Utility District since its inception, his talents and achievement helped fashion the District into the real constructive agency it has become.
>
> "His work was first the planning of a new distribution system for this area; then, Division Engineer on the District's great dam across the Mokelumne River; later, expert witness and leader of the District's engineering staff in important and far-reaching litigation; as General Superintendent he had charge of the Mokelumne water supply and the responsibility of bringing that water to the East Bay cities. His ability contributed greatly to the success of the District's undertaking.
>
> "Loyal, lovable and kind, in his passing the District has lost an able, conscientious official, his fellow workers a sincere comrade and friend, his family a devoted husband and father.
>
> "*Be It Resolved,* that to his family the Board of Directors of the East Bay Municipal Utility District extends its deep and heartfelt sympathy; and be it further resolved that a copy of this resolution be spread upon the minutes of this Board as a tribute to his memory and worth, and an engrossed copy thereof sent to his family."

Mr. Grunsky was married on January 9, 1913, to Hazel Kathryn Palmanteer, of Oakland. He is survived by his widow and two children, Kathryn Elizabeth Grunsky and Carl Ewald Grunsky III, and by his younger brother, Eugene L. Grunsky, M. Am. Soc. C. E.

He was a member of the Alpha Tau Omega Fraternity, the Commonwealth Club, and the Engineers Club of San Francisco.

Mr. Grunsky was elected a Member of the American Society of Civil Engineers on June 19, 1922.

HANS JORGEN HANSEN, M. Am. Soc. C. E.[1]

DIED NOVEMBER 4, 1938

Hans Jorgen Hansen was born in Aarslev, Fyn Island, Denmark, on February 14, 1871, the son of Rasmus and Mette Kathrine (Knudsdatter) Hansen. His parents died when he was a young boy, and at the age of fifteen, his older brother, realizing that Hans' chances for securing an education and obtaining employment were much better in the United States, arranged passage for his brother and himself. Hans was ambitious, found employment, and earned the money to defray the expenses of his early education and to prepare himself for college.

He attended Valparaiso University at Valparaiso, Ind., the Y. M. C. A. evening schools at Hartford, Conn., and in 1903 received the degree of Bachelor of Science in Civil Engineering from Armour Institute of Technology, at Chicago, Ill.

Following his graduation he was employed by the Hall Bascule Bridge Company as a Draftsman; the Strauss Bascule Bridge Company as a Draftsman and on field work; by Vierling McDowell and Company on shop detailing; and by the late W. M. Hughes, M. Am. Soc. C. E., as Detailer and Designer. His experience with these firms gave him a thorough training in the detailing and designing of bridges and other concrete and steel structures.

On May 6, 1906, he entered the service of the Chicago, Milwaukee, and St. Paul Railroad Company as a Draftsman; was promoted to Squad Foreman on July 1, 1915; and on February 1, 1917, was made Office Engineer in charge of the designing, detailing, and estimating of steel, wood, and concrete structures, which position he held until his death.

His work was of a highly diversified character, and included the design of some very large structures. He was an able designer. Thoroughly versed in precedents and standard practice, he also possessed a high order of initiative and resourcefulness which gave him marked advantage in dealing with situations that presented unusual difficulties. He examined with great care each factor of a problem, however complicated, and visualized, with accurate perspective, the project as a whole; but he was always open for suggestions consistent with the problem in mind.

In expressing his views orally, or in writing, Mr. Hansen was deliberate, clear, and precise, and was highly esteemed for his ability to draw sound conclusions. He held the respect of his fellow men and was genuinely liked by all with whom he came in contact. He was modest and retiring, always considerate of all those under his direction, helpful to his associates, just and generous in his dealings with every one.

---

[1] Memoir prepared by W. H. Penfield, M. Am. Soc. C. E., in collaboration with W. S. Lacher, Assoc. M. Am. Soc. C. E.

Among the many structures designed under his direction were the pontoon spans in the bridges across the Mississippi River at Prairie du Chien, Wis., and Wabasha, Minn. Very few bridges of that type for conveying heavy railroad traffic have been built. The application of the principle of the pontoon to heavy railroad loadings imposed difficulties that entailed the adoption of many unusual expedients. One of these pontoon spans was described in a paper that Mr. Hansen presented before the Western Society of Engineers on November 8, 1915.

He became a member of the American Railway Engineering Association in 1920, and took an active interest in its work.

In September, 1924, he asked for a leave of absence from the Railroad in order to take up work that would enable him to become more intimately acquainted with construction methods, and he returned to service in September, 1925.

He was a man of excellent habits, an indefatigable worker, devoted to his duty; and he encouraged and stimulated the efforts of others.

In the death of Hans Jorgen Hansen the Chicago, Milwaukee, St. Paul and Pacific Railroad Company has lost an employee whose loyal service has left a deep impression on all with whom he worked.

He was married at Waupaca, Wis., on September 26, 1907, to Louise Sorensen of Neenah, Wis., who survives him.

In 1912 he became a member of St. Ansgars Lutheran Church, which in 1927 was absorbed by the Danish Trinity Lutheran Church. He served both churches as a member of the Board of Trustees.

Mr. Hansen was elected a Member of the American Society of Civil Engineers on March 11, 1919.

ALFRED HANSON HARTMAN, M. Am. Soc. C. E.[1]

Died September 24, 1938

Alfred Hanson Hartman was born at Wilmington, Del., on February 26, 1879, the son of John Robinson and Laura V. (Hanson) Hartman. He was a direct descendant of Major Peter Hartman who served as Aide-de-Camp to General George Washington at Valley Forge.

Mr. Hartman was educated in the Public Schools of Wilmington and attended Delaware College from which he received the degrees of Bachelor of Civil Engineering in 1900, and of Civil Engineer in 1905. Strong and well built, he was interested in all branches of athletics while at college.

During the Spanish-American War, he was a Corporal in Company M, First Delaware Infantry, but he did not see service in Cuba.

---

[1] Memoir prepared by Gustav J. Requardt, M. Am. Soc. C. E.

Mr. Hartman began his professional career in the summer of 1899. He became a Rodman on a survey party for the New York Shipbuilding Company at Camden, N. J. During the summer of 1900 he was Transitman on track work for the Central Railroad Company of New Jersey. In 1900 and 1901 he was with the Kansas City Southern Railroad Company as Engineer-Inspector on a girder and drawbridge at Lake Charles, La., and on the foundations and abutments of a five-span bridge across the Illinois River.

In June, 1901, Mr. Hartman returned to Delaware to act as Assistant Engineer and Superintendent of construction for the late T. Chalkley Hatton, M. Am. Soc. C. E., on extensions to the sewerage systems of Wilmington and Milford, Del., and on the construction of a complete water-works for Seaford, Del. From December, 1901, to March, 1903, he was Assistant Engineer of the Maryland Division of the Pennsylvania Railroad Company, in charge of many preliminary and location surveys and on the construction of track elevation and bridge work through the City of Chester, Pa.

Mr. Hartman was employed by the Du Pont Company from 1903 to 1906 as Engineer of Construction in responsible charge of surveys, design, and construction of a dam across Brandywine Creek, Pa.; a slow sand-filter plant; several sewage-treatment plants; and a powder mill. He was also in charge of sanitary improvements along Brandywine Creek, and he made surveys and studies with a view to the improvement of the company's water-power properties.

In 1905 the officials of the City of Baltimore, Md., began organizing the forces of the Baltimore Sewerage Commission to undertake the design and construction of complete sanitary and storm-water systems, interceptors, outfalls, and a sewage treatment plant for the city. Mr. Hartman entered the employ of the Commission as an Assistant Engineer in 1906, shortly after construction work had started. He remained with the Commission until the completion of its program in December, 1915.

When its sewerage work started, Baltimore had few private sewers and drains and the streets were mostly paved with cobbles. Kitchen, bath, and laundry wastes were permitted to flow in the street gutters, and as there were few street inlets, this water flowed for great distances. At the completion of its work, the Commission had built 626 miles of sanitary sewers and 134 miles of storm-water drains and had expended about $23 000 000; it had connected most of the existing houses to the separate sanitary system, had built complete storm-water drains to remove storm flows from the street gutters, and had intercepted sanitary sewage and conducted it to a treatment plant located some 6 miles beyond the city limits at Back River in Baltimore County, Maryland.

Mr. Hartman rose rapidly in the personnel of the Commission, being assigned to surveys, design, and supervision of construction of the storm-water system. He was appointed Division Engineer of the Storm Water Division on August 15, 1910, which position he held until the completion of the work. The works designed and constructed under Mr. Hartman's direction included tunnels, drains through deep cuts and in soft ground supported on piles, and many types of street inlets, several of them of original design. Many of the standards of construction used at the present time by the City of Baltimore are those originally proposed by his Division of the Sewerage Commission.

The Jones Falls Diversion Tunnel and Conduits were built under Mr. Hartman's direction. Jones Falls is a stream of about 35 sq miles water-shed and flows through Baltimore to empty into tide-water in the harbor. Storm flows had topped the side walls many times, flooding streets for blocks on each side of the stream. The stream was completely covered from Mt. Royal Avenue to near the harbor, and no flooding has occurred since this construction. This was a major improvement of the City, and its features have been studied by many engineers.

In 1916 Mr. Hartman was retained as Consulting Engineer by the Consolidated Engineering Company of Baltimore, in connection with tunnel work the Company was doing for the Southern Railroad in North Carolina. In the early part of 1917, Mr. Hartman came with the Company, devoting his entire time to it. On February 9, 1918, Mr. Hartman was elected a Director and continued as a Director of the Company until his death. On the same date he was made General Manager of the Engineering Department, which position he held until February 19, 1927, at which time he was elected Third Vice-President, and continued in that position until February, 1938. He was then elected Second Vice-President, which office he held at the time of his death.

Under Mr. Hartman's direction, the Consolidated Engineering Company rehabilitated the Asheville Division of the Southern Railway, which was made necessary by the floods of 1916 and 1917. This work included the restoration and building of a number of bridges and tunnels; the sedimentation basins at Monroe, Va., the under-pass at Greensboro, N. C., and the 17½-mile cut-off in Tennessee from Bullsgap to Leadvale for the Southern Railway Company; bridges at Thurmont, Md., for the Western Maryland Railway Company and the State Roads Commission, and the Gay Street Bridge in Baltimore for the Pennsylvania Railroad Company; new track work and bridges for the Baltimore and Ohio Railroad Company at Romney, W. Va., caused by damages to the system by the 1936 flood; the dam and reservoir for the Frederick, Md., water supply, the filter plant at York, Pa., the Rodney Street Reservoir at Wilmington, and the Ashburton Pumping Station for the Baltimore Water Department; the foundations for the new Department of Commerce Building in Washington, D. C., and many other structures. He was also associated in an advisory capacity with many other projects upon which the Company was engaged.

Mr. Hartman was a member and Past-President of the Engineers Club of Baltimore, and a member and Vice-President of the Maryland Section of the American Society of Civil Engineers. He took an active interest in the affairs of these organizations during the whole of his membership. He was a member of the Civitan Club of Baltimore, the Baltimore Country Club, and the Emmanuel Episcopal Church of Baltimore. He had lived in Balitmore continuously since 1906.

Mr. Hartman was an authority on foundations, tunnels, drainage, and railroad track work, and on the planning of construction methods and equipment. During his career he trained many young engineers. He will be remembered by them because of his kindly, retiring nature, and his vast fund of technical experience.

On June 15, 1904, Mr. Hartman was married to Annie G. W. Summers at Elkton, Md. He died in Oakland, Calif., while on a visit with his family. He is survived by his widow; his children—Elizabeth Hartman Ward, Nancy G. W. Rumsey, and Wilmon Whilldin Hartman; and by his grandchildren—Nancy G. W. Ward, Alfred Gilfry Ward, and Elizabeth Hamilton Rumsey.

Mr. Hartman was elected a Junior of the American Society of Civil Engineers on December 6, 1904; an Associate Member on December 5, 1906; and a Member on October 1, 1912.

JAMES NOBLE HATCH, M. Am. Soc. C. E.[1]

Died November 11, 1938

James Noble Hatch was born on January 3, 1868, at Saint Helena, Napa County, California, the son of Lucius Lucian and Sarilda Berry (Hornbeck) Hatch. After attending Grammar School and High School in his native State of California, he entered the University of Michigan, at Ann Arbor, Mich., in 1888, and was graduated with the degree of Bachelor of Science in Civil Engineering in 1892. In 1898 he was granted the degree of Civil Engineer and in 1909 was given the Masters degree of Mechanical Engineer.

His professional record was long and impressive, combining work in both civil and mechanical lines, in which he was equally proficient. After a year of preliminary engineering experience he became Instructor of Engineering at the Michigan Agricultural and Mechanical College, at East Lansing, Mich., and from then on engaged in active engineering work.

In 1894 and 1895 he was Assistant Engineer in the Maintenance of Way Department of the Big Four Railroad Company. He left the railroad to become Structural Engineer and Designer for the Carnegie Steel Company, the Pittsburgh Steel Company, and the Brown Hoisting Machinery Company, of Cleveland, Ohio, respectively, from 1896 to 1900. During this period, Mr. Hatch had charge of the design of tall steel buildings and coal handling plants, which were then coming into general use, both in the United States and abroad. He added considerably to their development along the best, and most practical, engineering lines.

In 1900 he passed a Civil Service examination, was appointed Superintendent of Construction and was assigned in this capacity to many important buildings for the United States Government. He remained in this position until 1902, at which time he joined the Engineering Staff of the American Bridge Company at Chicago, Ill., for one year. In 1903 he became associated with the consulting firm of Sargent and Lundy, of Chicago, in charge of the

---

[1] Memoir prepared by I. F. Stern, M. Am. Soc. C. E.

Structural Department. He remained in this position for more than eleven years in the design, construction, and operation of large, central, electric power stations throughout the United States. This work involved many difficult civil and mechanical engineering problems relating to the design of machinery, intake tunnels, bridges, foundations, structural work, chimneys, and other details. During this period, Mr. Hatch assisted greatly in the development of a type of self-supported steel stacks, on which he became a recognized authority.

In 1914 Mr. Hatch resigned his position with Sargent and Lundy and opened his own offices in Chicago as Consulting Engineer, on bridges, buildings and other structures, power plants, valuations, and general engineering service. Many clients availed themselves of his services and he maintained his offices until 1928, at which time he yielded to a long-cherished desire to return to his native State of California. In California, he devoted himself to literary work and to his orchards, but the lure of his profession, in which he had been so successful, was too great to be withstood, and in 1935 he accepted an appointment as Engineering Examiner for the Public Works Administration in California, which he retained as long as his health permitted.

Mr. Hatch combined with a great engineering ability, a natural inclination toward literary work. He was a frequent contributor to technical magazines, and was also the author of numerous sketches, essays, and poems, usually in a humorous vein, but exhibiting a deep philosophy.

During a busy life, Mr. Hatch was dearly beloved by his associates, not only for his sterling character, kindness and loyalty to his associates, but also for his quaint sense of humor which found expression in his whimsical sketches and poems. These have been collected and published under the title of "Mirthful Musings by Truthful James." Many of these poems were originally read at meetings of the Chicago Engineers Club, to whom Mr. Hatch was fondly known as its "Poet Laureate."

Mr. Hatch was a member of the Chicago Association of Commerce, the Western Society of Engineers, the Chicago Engineers Club, the National Electric Light Association, and the Pasadena Engineering Society.

In 1893, he was married to Lufanna Barber of Ann Arbor. He is survived by his widow; two daughters, Marion and Esther Lou; one son, Hadley; and a sister, Mrs. Anna Croall.

Mr. Hatch was elected a Member of the American Society of Civil Engineers on December 7, 1904.

CHARLES WILLIAM HAZELTON, M. Am. Soc. C. E.[1]

Died September 29, 1937

In recording the life story of any man who has completed a full and active career in his community, one finds that there is always some feature or some phase of that life which has left its lasting impression. With such a remembrance whether faint or vivid, whether it be a spoken word, an ideal, or a structure of brick and stone, there is preserved the character and spirit that guided his life's endeavors.

---

[1] Memoir prepared by C. E. Hazelton, Esq., Turners Falls, Mass.

For Charles William Hazelton there was one absorbing interest during his most active and creative years. The control and development for human service of the Connecticut River at Turners Falls, Mass., was a project with which he was intimately associated at the beginning and which was basically modified and greatly expanded under his direct supervision. After relinquishing the responsibilities of active management, he had the rare distinction of seeing created such a wider and greater field of use and service as was literally inconceivable to the originators, but of which he had had a vision and had prepared the way.

Although time and change have so greatly altered the scene and design of those earlier years of application, there still remain in the traditions and annals of the organization that Mr. Hazelton served, in the facilities and aspects of a community which he helped to bring into being, many mute but characteristic evidences of a spirit and personality which mingled inspiration with achievement during more than forty years of leadership.

In a valley indelibly associated for so many years with the struggles and hardships of gaining an established settlement; and at the very spot where occurred one of the most destructive conflicts of that period, there arrived soon after the Civil War, Alvah Crocker, of Fitchburg, Mass., a genius of industrial promotion and development. Disregarding the rights of picnic parties and sightseers at the brink of the Great Falls and dislodging the ancient gate-keeper at the canal locks, he commanded a new era of work instead of lassitude for the river which had for so many centuries been its own master—and still is at times. With the construction of a dam, head-gates, and canal, for harnessing the river's power, there appeared, almost overnight, factories, stores, a hotel, apartment blocks, schools, and churches—in fact, a city had been set down in a scene so recently a hill and woodland retreat. Although it is true that many of the aspects of civic attainment were wholly on the surveyor's plans, or in a beautifully lithographed prospectus, there had been brought into being the Town of Turners Falls, new born among ancient neighbors with the lusty cries and rough behavior typical of a Western mining bonanza.

Charles William Hazelton, the son of Charles and Hannah (Sargent) Hazelton, was born at Plymouth, N. H., on October 31, 1848 When a boy, the new railroad—the Boston, Concord, and Montreal—had claimed his early interest. When work on his father's farm on the outskirts of the village or freedom from school would permit—and sometimes without such permission—he would be found at the railroad station located in the old Pemigewasset Hotel, or around the roundhouse which housed the glittering iron horses of that day. In fact, his first gainful employment at the age of twelve was as a train boy selling apples from the farm orchard on the run between Plymouth, and Concord, N. H. With the help of the night operator he learned telegraphy and unofficially was allowed to send and receive some of the more unimportant railroad orders. Although there were some parental objections to his "hanging around the depot," this interest brought him what turned out to be his opportunity, as it was in the railroad yard at Plymouth that he met William P. Crocker, brother of Alvah Crocker, then a Consulting Engineer for the Concord and Montreal Railroad Company. At the age of seventeen years Mr. Hazelton was employed by Mr. Crocker as a Rodman on the surveys for the Whitefield, Woodstock, and Northern New Hampshire, and the Boston, Concord, and Montreal Railways—the first rung in the ladder of a civil engineering career. He was fortunate in his association during formative years with so eminent a civil engineer of that period.

As an Assistant to the Engineer in charge of surveys made during 1867 and 1868, preliminary to the actual construction, Charles Hazelton, at the age of nineteen years, was climbing over the rocks and cliffs about the Great Falls and cutting his way through the brush and forest surrounding it with measuring chain and sighting rod, and with probably no thought that the primitive scene before him was to be his future life's environment. Apparently, at this time, civil engineering had already gained his interest and allegiance as he continued with William P. Crocker, the Engineer in charge of the new project, as Assistant on the same work that he had started a few years earlier, and on various railroad surveys and reconnaissances in Northern New Hampshire.

With the completion of surveys and detailed plans, work on the dam, head-gates, and canal, was begun during the following year—1868—and for two years Mr. Hazelton was engaged in supervising their construction from the plans which he helped create. This was a period of exciting interest in the growth of the project. With the influx of laborers, masons, and carpenters, temporarily living in the two dwelling houses and the home of the former gate-tender, and with the promised location of the first mills for using the new water power, added emphasis was laid on the prospective attractions of the new City of Turners Falls. The wide avenues and cross-streets which had been shown in lithograph with such a geometrical and metropolitan design, were staked out and roughly graded and then with free railroad fares and dinners, the public was invited to participate, through the purchase of building lots, in the immediate realization of a vision. During this period, the young Assistant Engineer had many duties in addition to overseeing the construction work on the dam and head-gates. A water system for the new community, sewers, and even police and fire protection, had to be provided; all these required facilities came within his province. There had been no four or six years of technical school education for this young engineer, still in his minority, and problems of design and construction were only solved through the help of older and experienced men, the use of a few texts, and a native intelligence and aptitude for the work.

It was at this time that there came to Turners Falls a man of striking personality who was to have a profound influence on the course of Mr. Hazelton's life. As general contractor for the enlargement of the old canal and for the construction of many of the new factories and buildings, the late Bernard N. Farren, Fellow, Am. Soc. C. E., desired to secure a Resident Superintendent, and by amicable arrangement, Mr. Hazleton severed his connection with the Turners Falls Company and started to learn the details of contract construction. For three years he remained in Turners Falls for the completion of various contracts and then for the next four years, 1872 to 1876, his duties took him to different parts of New England where "Barney" Farren, as he was then called, had secured work for his organization. The most important of these contracts, all of which had their problems as well as many interesting features, included the construction of a railroad north from Worcester, Mass.; the removal of Fort Hill with corresponding filling of Back Bay, in Boston, Mass.; and the installation of a brick lining in the Hoosac Tunnel. During all the seven years of this association, Mr. Hazelton had his home with the family of Mr. Farren and between these two men of quite dissimilar ages, there resulted a close and enduring friendship.

In 1877, at the age of twenty-eight, Charles Hazelton gave up his position with Mr. Farren and formed a partnership with William Campbell, under the name of Campbell and Hazelton, for the purpose of conducting a contracting business on his own account. The firm was reasonably successful and constructed several buildings in Turners Falls, one of the first halls for the Moody Schools at Northfield, Mass., and as its largest and most important project, relocated a section of the railroad a short distance east of Millers Falls, Mass., with a corresponding change in the bed of the Millers River at that point. However, the partnership was dissolved by mutual consent about two years after its formation.

At this time, progress of the water-power and industrial development at Turners Falls had reached the stage where problems of maintenance, operation, and general policy predominated, with the consequent necessity for an active and progressive resident management. It was not coincidence that Charles Hazelton was selected, in 1880, by the officials of the Turners Falls Company as Engineer for the properties; his earlier connection with the Company had demonstrated an ability and character that made the choice a natural one.

Thus, at the age of thirty-two years, he assumed the rôle of guardian for one of Nature's greatest resources—hydraulic power—with a responsibility for continued service to human needs that knows no day of rest. The river was in harness, but not subdued.

In the period that had elapsed since its establishment, Turners Falls had given up the hopes of immediate expansion to civic proportions and had settled down to normal growth as a typical New England industrial town. Self-centered, as were most small communities at that time, but with a spirit of aggressiveness sponsored by its unique background, the town thrived. Churches, schools, banks, and stores were established, an extensive sewerage system and a highly satisfactory water supply were installed—all in less than ten years from the time the first prospectus was printed. In all these enterprises Charles Hazelton had his part, not only because he had in his official position a partial responsibility for their success, but because he possessed, in addition, an inherent and characteristic desire to be of service as a citizen and as a friend.

He had already formed two personal associations of major importance in his career—one with William Crocker, and one with Bernard Farren—and now a third contact was to bring him not only an intimate friendship and a community of interest, but financial independence as well. In Pelham, Mass., Eugene Bartlett had established a small factory for the manufacture of fishing rods, and with a prosperous business he sought new capital and associates for expansion. Possibly through a mutual liking for the piscatorial pastime, the contact was made and a new corporation was organized with a factory near Turners Falls. The Company continued to be successful for many years although the activity of Mr. Hazelton in this business was always incidental to the larger responsibilities which he had previously assumed.

Although from 1880, when he had returned to the Water Power Company, there had ensued a continuing period of more gradual expansion both in the utilization of the energy created and in the community that had been fostered, it was also a period of adjustment and revision with many problems of policy and administration to be worked out by both Company and townspeople. The original indentures for the sale of water power had provided for a rental of $5 per yr per hp, with use permitted for 24 hr per day and extending for a term of 999 yr. In the light of present-day conditions, this contract seems astonishing in its low cost and privileges. However, the mill owners, in an eagerness to expand their plants and increase production, were careless in observing the limitations of the contract, and it became a major part of Mr. Hazelton's duty to regulate and apportion the use of water both as to legal quantities and under conditions of diminished river flow.

In 1890, he was made Treasurer and Clerk of the Water Power Corporation, in addition to his position as Engineer for the properties, and with these increased responsibilities there came opportunities to prepare the way for the larger development that few visioned at that time.

Although the Company had benefited materially through supplementing the old indentures for permanent rights with new contracts for the sale of surplus water, Mr. Hazelton had realized that the most efficient use of the natural drop of the Connecticut River in the vicinity of Turners Falls necessitated the eventual abandonment of the original plan and the substitution of a radically different and much more extensive design.

The first step was the acquisition of various tracts of land and flowage rights, a long and difficult process requiring considerable tact and diplomacy. Again, came the period of preliminary surveys, of plans and computations, all with a definite goal in mind. The vast strides being made by the electrical industry at this time, especially the long-distance transmission of power, had a vital effect on these new considerations, and as a step toward a still distant horizon, the Directors of the Turners Falls Company, at Mr. Hazelton's suggestion, authorized, in 1904, the widening, deepening, and extension of the original power canal, together with the construction of a hydro-electric generating plant at Turners Falls.

With this additional power capacity there came new problems of operation and management and although a relatively small expansion, it represented an entirely different type of use and service. No longer would it be necessary to locate factories on the river bank in order to take advantage of its energy, for with electricity the water power could be carried to distant localities for manufacturing, lighting, heating, and a multitude of future uses unthought of at that time. The effect was far-reaching. The Company's field was broadened, and the former surveyor and hydraulic engineer now in the full maturity of his career was faced with the new technical problems of electrical generation and distribution.

During the next eight years, Charles Hazelton as the Managing Executive was to be responsible for the second rebirth of a century-old organization. The navigation canal and locks around the Great Falls of 1791 had been the basis of Alvah Crocker's realized dream of an industrial center and now the Water Power Company which he founded was on the threshold of an even greater service to human needs—a true public utility was envisioned. Fortunately, at this period of change and adaptation, there had entered the employ of the Company a young man named Fred C. Abercrombie whose help as Mr. Hazelton's Assistant during these trying years was to prove invaluable.

While the first small electrical development was being ushered into the world with attendant problems of refinance, public relations, and a market appetite, the larger plan based on Mr. Hazelton's earlier studies and recommendations, was gaining wider support and more general interest.

As its extent and possibilities would necessitate new resources of capital and a revised managerial organization and with the feeling that the first step in the hydro-electric development at Turners Falls was in successful operation, Charles Hazelton, at the age of sixty-four, and after forty-four years of active engagement in the Company's affairs, requested that the responsibilities of the expanded program be transferred to others, and, in 1912, he retired as Treasurer and Engineer of the Company. However, for the next twenty years, he acted as a Director and in an advisory capacity for the Turners Falls Power and Electric Company and Associated Companies. His service to this interest thus covered a period of sixty-four years.

Although his retirement had marked the close of active participation in what had been his life's major theme and should have entitled him to a well-earned rest, it was in character that Mr. Hazelton now felt it necessary to devote more time and attention to his interest in the fish-rod business—the Montague City Rod Company—and to assume, when requested, various responsibilities of a semi-public nature. He served as President of the Connecticut Valley Street Railway Company from 1912 to 1922; as Trustee of the Western Massachusetts Companies from 1927 to 1934, and as President of the Crocker National Bank, at Turners Falls, from 1920 to 1930.

Fortunately, too, his release permitted more indulgence in various avocations which had been kept in the background during previous years. Chief among these was a deep interest and keen enjoyment in flowers, ornamental plants, and even vegetables, as evidenced by the greenhouse and garden that he maintained at his home. Foreign travel had always been a dream which now he was able to realize, and it is interesting to note that his inclinations preceded the present trend toward Southern travel. On numerous different trips, he visited most of the Caribbean Islands, all the countries of Central America, and spent a most enjoyable two months in Brazil and the Argentine Republic. Incidentally, and again self-taught, he acquired a reading knowledge of the Spanish language.

Although he had been denied the benefits of much more than a grammar school education, he seemed to have a natural inclination to history and languages. His own lifetime covered an industrial and economic transition in the Connecticut Valley, and the events and personalities of that period were vivid in his recollection and descriptions. The geological formations of the Valley were of great interest to him, this latter study undoubtedly being influenced by his profession.

While still with the Turners Falls Company he started an intensive study of the German language and, with a system of his own and with lessons from native Germans in Turners Falls, he acquired a reading and speaking command of that language.

Although in his early years there had been little time for the recreational relaxations now considered so essential, he did take pleasure in ice skating and fresh-water fishing both of which, either by coincidence or design, were associated with the major interests in his life.

Mr. Hazelton was active in political and social life. He was a Representative in the Massachusetts State Legislature, a Commissioner in Franklin County, a member of the School Committee in the Town of Montague, a Delegate of the National Republican Convention, a Senator of the Massachusetts State Legislature, and a member of Pocomptuck Valley Memorial Association. He was also very active in the Masonic Order, being a charter member of the Mechanics Lodge of Masons, and a member of the Franklin Arch Chapter, the Titus Strong Council, and the Connecticut Valley Commandery. He was a member of the Aleppo Temple of the Mystic Shrine in Boston, and a member of the First Congregational Church in Turners Falls.

On May 12, 1870, he was married to Ella Wilder, of New Bedford, Mass., who predeceased him. On December 1, 1917, he was married to Grace Frensz, of Houston, Tex., who survives him, together with their adopted daughter, Mary Margaret; also one son and two daughters by his first wife—Charles Edward, Ella Macomber, and Helen Wilder Hazelton.

In summation, the life story of Charles William Hazelton, of Turners Falls, is the history of an institution and of a town, as physically, economically, and socially the three are as one. With the release from all responsibilities on September 29, 1937, at the age of eighty-nine years, there passed on a man whose life had been well spent.

Charles William Hazelton was elected a Member of the American Society of Civil Engineers on January 7, 1891.

THOMAS HEATLEY, M. Am. Soc. C. E.[1]

Died October 27, 1938

Thomas Heatley, Jr., was born at Birkenhead, England, on October 6, 1865, the son of Thomas Heatley of Pettigo, County Donegal, and Elizabeth (Sproule) Heatley of Kesh, County Fermanagh, Ireland. About 1870 the family emigrated to New York, N. Y., where Thomas, Jr. attended the Public Schools. Shortly after graduation, he began a long and interesting career in the building art, starting as an apprentice bricklayer for his father (who was a mason building contractor), and serving successively through the ranks as mechanic and eventually professional engineer. These occupations are attested by Life Membership No. 80 964 in the Bricklayers', Masons', and Plasterers' International Union.

After some fifteen years spent in the practical art as Apprentice, Journeyman, Foreman Mason, and eventually in partnership with William Bailey, as mason contractor (during which time he laid brick in many of the then prominent building structures, including the original Bloomingdale Asylum at White Plains, N. Y.), Tom Heatley began an active career in the field of public building supervision. In 1895, he was appointed Special Inspector in the then Department of Buildings of New York City, serving on the same staff with Rudolph P. Miller, M. Am. Soc. C. E.—who later became Superintendent of Buildings—and Thomas Lamb, who as Architect later designed and constructed many of the now prominent theater structures in New York City.

From 1895 until his retirement from the city service on June 30, 1934, Tom Heatley worked up through the grades of Civil Service, serving successively as Inspector of Iron and Steel, Engineer Inspector, General Inspector in Charge of Field Force, Plan Examiner, Engineer in Charge of tests of materials, Assistant Engineer, and finally acting Chief Engineer under Superintendent Patrick J. Reville. The latter part of this career, subsequent to 1902, was spent in the then Bureau of Buildings, Borough of the Bronx, New York City.

Supplementing his practical experience with a strong latent desire for theoretical knowledge, Tom Heatley attended evening technical courses in the Brooklyn Polytechnic Institute, Brooklyn, N. Y., and with the aid of his many professional friends, devoted much time to study supplemented by technical committee work for the American Society for Testing Materials, in which connections his practical recommendations proved of lasting value.

During this decade of the early Twentieth Century, rapid gains and advances were made in the art of building, involving the use of protected iron and steel and reinforced concrete in the development of skyscraper construction. Through his official connection with the Bureau of Buildings, Borough of the Bronx, in charge of tests of new materials and methods of construction, Mr. Heatley took an active part in this pioneering stage. He was closely associated with Mr. R. P. Miller and Prof. Ira H. Woolson in the conduct of their many fire and strength resistance tests of fireproof construction, and interested himself actively in the research and experimental work of the epoch. Subsequently, in his official capacity, he represented the City of New York in the investigation and testing of European materials of construction for importation into the United States, and made trips of inspection to Belgium, France, Holland, and Germany for purposes of study and research.

---

[1] Memoir prepared by George E. Strehan, Assoc. M. Am. Soc. C. E.

During his forty years of active building supervision with the City of New York, he acquired a wealth of human, as well as technical, experience. With an inimitable skill in verbal expression and narrative, inherited from Irish Ancestry, he entertained friends and associates with astounding tales of building and engineering art as it was practiced in this somewhat hectic period of speculative growth. A keen sense of humor and thorough human understanding eased the official path in the enforcement of law and endeared him to his many friends, associates, and public alike.

On June 16, 1894, Mr. Heatley was married to Adele W. Engle at Long Branch, N. J., who survives him.

Mr. Heatley was elected an Associate Member of the American Society of Civil Engineers on January 15, 1917, and a Member on April 21, 1930.

IRA GRANT HEDRICK, M. Am. Soc. C. E.[1]

Died December 28, 1937

Ira Grant Hedrick was born at West Salem, Ill., on April 6, 1868, the son of Henderson and Mary Ann (Bryan) Hedrick. His parents moved to Fayetteville, Ark., and there he attended the University of Arkansas (then called Arkansas Industrial University) from March, 1890, until he was graduated in December, 1892, with the degree of Bachelor of Civil Engineering. He was married at the time he entered this school, and before his graduation he was the father of two children. He supported his family and made his way through school by working during his spare time at anything he could find to do. Mrs. Hedrick nobly assisted him by keeping boarders. The community was small and jobs were scarce. Mr. Hedrick's principal employment was teaching during vacation periods, which he prolonged as much as practicable by leaving before the close of the school year and entering as late as he could after the beginning of the next session. In spite of these handicaps, he completed the four-year engineering course in less than three years and always stood at the head of his class. For a long time after his graduation, faculty members were wont to cite his scholastic record as being the best in the history of the school.

---

[1] Memoir prepared by Victor H. Cochrane, M. Am. Soc. C. E.

Immediately after his graduation Mr. Hedrick entered the employ of the late J. A. L. Waddell, Hon. M. Am. Soc. C. E., at Kansas City, Mo., and was associated with him until 1907, except for a period of service with the Kansas City, Pittsburg and Gulf Railroad Company (later, the Kansas City Southern), in 1898 and 1899, as Assistant Chief Engineer. Mr. Waddell's practice was chiefly in the field of bridge design and construction, and here Mr. Hedrick found work suitable to his talents. He soon became Mr. Waddell's Principal Assistant. His design calculation sheets were models of neatness and accuracy. In those days the art of bridge design was developing rapidly, and Mr. Hedrick was of great assistance to Mr. Waddell in the preparation of the latter's pioneer book, "De Pontibus." In 1899, Mr. Hedrick entered into partnership with Mr. Waddell in the firm of Waddell and Hedrick. Structures designed by this firm included a bridge over the Missouri River, at Omaha, Nebr., another over the same stream, at St. Charles, Mo., the Fraser River Bridge, at Westminster, B. C., Canada (having an unusual "spread" span), bridges for the Vera Cruz and Pacific Railroad Company, and for other railroad companies, a bridge over the Red River for the Kansas City Southern Railway Company, and the Sixth Street Viaduct, in Kansas City (later, called the Intercity Viaduct).

Mr. Hedrick's resourcefulness was demonstrated during and after the Kaw River flood of 1903. One span of the bridge carrying the main flow line of the Kansas City Water-Works was washed out, and the city was entirely without a supply of water. The firm of Waddell and Hedrick was commissioned to construct a temporary bridge to restore service, and Mr. Hedrick took charge of the construction work. Using old street railway cables and such odds and ends of materials as could be procured, and working continuously day and night, the bridge was completed in about eight days. In this same flood, two 200-ft riveted spans of the Kansas City Southern Railway Bridge were carried away, and one span landed about 600 ft down stream. Mr. Hedrick devised ingenious means for righting these spans and restoring them to position intact.

At the turn of the Twentieth Century, pin-connected trusses were in general use for all but the shortest spans. Mr. Hedrick early saw the advantages of riveted trusses and was a pioneer in their development. In 1904, he designed 300-ft riveted spans for the Intercity Viaduct crossing of the Kaw River, at Kansas City.

In 1907 Mr. Hedrick withdrew from the firm of Waddell and Hedrick and opened an office of his own in Kansas City. At the same time he took over the management of the affairs of the Company which owned and operated the Intercity Viaduct. Three years later the writer joined Mr. Hedrick in the firm of Hedrick and Cochrane. Among the structures designed by this firm were the Dallas-Oak Cliff Viaduct; bridges over the Kaw River, at Lawrence, Kans., and Kansas City; the Arkansas River Bridge, at Pine Bluff, Ark.; two bridges and a dam for the City of Cedar Rapids, Iowa; the Red River Bridge, at Shreveport, La.; and several bridges for about six other railroad companies.

Upon Mr. Cochrane's withdrawal from the firm in 1916, Mr. Hedrick and his son, Arly, continued the business as Hedrick and Hedrick. Mr. Arly Hedrick volunteered for service in the 110th Engineers, was commissioned a Captain, and served with distinction in France, being decorated for bravery in action. In March, 1919, while in Brest, France, awaiting transportation to America, Captain Hedrick contracted influenza and died. Ira Grant Hedrick never recovered from this blow, and thereafter did not try to maintain a large engineering organization. He was content to accept only one or two major engagements at a time, and he removed his office several times, in order to give personal attention to the work in hand.

After closing his Kansas City Office in 1923, Mr. Hedrick removed to Portland, Ore., and there was first associated with Robert E. Kremers, and, later, with William Durkee Smith and Lloyd Garner Frost, Assoc. M. Am. Soc. C. E. Mr. Hedrick and Mr. Frost, under the name of Hedrick and Frost, conducted an engineering business in New Orleans and Shreveport, La., for about three years (1925–1927). Mr. Hedrick removed to Arkansas and stayed there during the remainder of his life, except for a brief period of residence in Oak Point, Wash. In Arkansas, Mr. Hedrick's office was situated in Hot Springs National Park.

Among the structures designed by Mr. Hedrick and his associates during the period 1922–1928 were two bridges over the Arkansas River, one at Little Rock, Ark., and the other at Fort Smith, Ark.; two bridges over the Willamette River, at Portland; a bridge over the Atchafalaya River, at Simmesport, La., for the Louisiana Railway and Navigation Company; the Lake Worth and Royal Street Bridges, at Fort Worth, Tex.; the Back Bay Bridge, at Biloxi, Miss.; and the Main Street Viaduct, in North Little Rock, Ark. For the Arkansas State Highway Department Mr. Hedrick designed two bridges over the Red River, three over the White River, one over the Ouachita River, and three over Lake Hamilton. His last engagement was that of Examining Engineer in the Little Rock Office of the United States Public Works Administration.

The period of forty-five years during which Mr. Hedrick carried on his professional activities was characterized by great advances in the art of bridge design. He kept himself informed concerning the latest developments, and contributed no little to the progress in this field. He was not inclined to write technical papers but encouraged his associates to do so. His engineering designs were brilliantly conceived and were always developed with a view to economy and practicability in construction. His advice was frequently sought by contractors in regard to difficulties in pier sinking and other problems of construction.

In recognition of his professional attainments he received from his Alma Mater the degree of Civil Engineer in 1901, and from McGill University, at Montreal, Que., Canada, the following degrees: Bachelor of Applied Science, 1898; Master of Science, 1899; and Doctor of Science, 1905. He was elected to Tau Beta Pi Fraternity in 1915. He was a life member of the Masonic Order, and a Shriner. He was also a life member of the Benevolent and Protective Order of Elks.

Mr. Hedrick possessed a forceful and magnetic personality and had a great capacity for making friends. He was always fair to his associates and just in his professional decisions. His great ability was quickly perceived by those with whom he came in contact, and he ever retained the loyalty of his associates.

He is survived by his widow, the former Mary E. Bryan, to whom he was married at Kansas City, on September 22, 1926. In 1889, he was married to Louise Luther, of Fayetteville, Ark. To this union three children were born: Arly Luther Hedrick, the son who died in France; Marie (Mrs. Morton Steiger), and Louise (Mrs. Russell Cowgill). In 1909, after the death of Mrs. Hedrick, Mr. Hedrick married her sister, Addie M. Luther. Two children of this union survive: Ira Grant Hedrick, Jr., Jun. Am. Soc. C. E., and Betsy Carolyn. In 1918, at Liberty, Mo., Mr. Hedrick was married to Della M. Threlkeld. Mr. Hedrick is also survived by his mother, three brothers, Dennis, John, and Gideon; and two sisters, Della, and Mrs. C. A. Wofford.

Mr. Hedrick was elected a Junior of the American Society of Civil Engineers on October 3, 1893; an Associate Member on June 2, 1897; and a Member on November 7, 1900.

VICTOR KING HENDRICKS, M. Am. Soc. C. E.[1]

Died March 19, 1938

Victor King Hendricks died at his home in Oak Park, Ill., on March 19, 1938; the world was better for his having passed this way and a loser by his going. He was a man peculiarly gifted with those innate qualities of courtesy and kindliness to his fellow men, and all who knew him loved him for what he was.

Victor King Hendricks came from distinguished parentage and carried to a high degree the heritage he bore. He was born on May 28, 1869, at Indianapolis, Ind., the son of Abram W. and Sarah (Butler) Hendricks. In 1839 his father moved from Westmoreland County, Pennsylvania, to Madison, Ind., to study law with his uncle, the Hon. William Hendricks, Governor of Indiana, from 1822 to 1825, and, in 1866, he went to Indianapolis to join his cousin, the Hon. Thomas A. Hendricks, Governor of Indiana from 1873 to 1877, and Vice-President of the United States with President Grover Cleveland, from 1885 to 1889, one of the most distinguished sons of Indiana. His law firm was Hendricks, Hord, and Hendricks.

Victor Hendricks was educated in the Indianapolis public and private schools and was graduated from Rose Polytechnic Institute, at Terre Haute, Ind., with the degree of Bachelor of Science in Civil Engineering in 1889. He received the degree of Master of Science in 1900. He was very popular as a student, and entered into athletic and social activities. He was also an accomplished master of the banjorine.

---

[1] Memoir prepared by a Committee, consisting of Theodore L. Condron, M. Am. Soc. C. E., *Chairman*, and Alonzo J. Hammond, Past-President, Am. Soc. C. E., and F. G. Jonah, M. Am. Soc. C. E.

Immediately following his graduation, Mr. Hendricks spent some time with the Edgemoor Bridge Works, at Wilmington, Del.; but shortly thereafter he followed the urgent invitation of a classmate and went to the State of Washington, where he was engaged for several years in railroad construction by the Fairhaven and Southern Railway Company and the Bellingham Bay and Eastern Railway Company, experiencing throughout this period some of the trials of a locating engineer in a mountainous terrain.

In 1893, he returned to Indiana with the La Fayette and Indiana Bridge Companies, and then engaged in railroad engineering which was to be his principal life work, as Assistant Engineer on the Terre Haute and Logansport Division of the Vandalia Railroad. He was promptly advanced to the position of Engineer, Maintenance of Way, and Principal Assistant Engineer, retaining his connection with the Vandalia Railway Company until 1902. During this period he displayed a keen interest in the advancement of the art of railway engineering in all its phases.

Leaving the Vandalia Railway Company, Mr. Hendricks became Assistant to the Engineer, Maintenance of Way, of the Baltimore and Ohio Railway (System) and, later, Division Engineer. In 1907, he joined the staff of the St. Louis-San Francisco Railroad (System) as Assistant Engineer, Maintenance of Way, and he remained with that Company in various capacities for about thirteen years; as Office Engineer (1909–1911); Principal Assistant Engineer (1911–1913); Assistant Chief Engineer (1913–1918); and Chief Engineer under the United States Railroad Administration (1918–1919). During the same period he was also with the Missouri Kansas and Texas Railway Company. When his former chief came back from Army Service in France, in 1919, Mr. Hendricks returned to the position of Assistant Chief Engineer. In the succeeding years of 1920–1921, he was Assistant Manager and Field Engineer in the Department of Liquidation Claims, of the U. S. Railroad Administration at St. Louis, Mo., and, later, he became Regional Engineer for the Southwestern Region until that office was abolished in 1921.

Moving then to Chicago, Ill., Mr. Hendricks was first with the Illinois Appraisal Company, and, later, became associated with Rufus W. Putnam, M. Am. Soc. C. E., as Railroad Engineer in the studies for the Harbor Plan of Chicago for the Commercial Club of that city.

During 1928, to and including 1931, he was associated with Walter A. Shaw, M. Am. Soc. C. E., in the preparation of plans for the grade separation of the Chicago and Northwestern Railway and the Chicago North Shore and Milwaukee Railroad (Electric), where they pass through the municipalities of Kenilworth, Winnetka, Glencoe, and Highland Park, in Illinois. This work included detailed estimates and the preparation of the case for presentation to the Illinois Commerce Commission.

After this engagement, Mr. Hendricks retired from active service except for occasional brief engagements.

He was married, on May 28, 1908, to Sue Ross, of Terre Haute, a very charming girl whom he had known during his college days. He is survived by his widow and two children, Victor K., Jr., and Alan Ross.

One of the writers emphasizes strongly some of Mr. Hendricks' personal characteristics, his industry and courtesy, and his thorough analysis of problems before reaching conclusions. According to Colonel Jonah: "These were some of the characteristics which brought him to my favorable notice while he was with the 'Frisco.'"

He was a life member of the American Railway Engineering Association. He was also a member of the Western Society of Engineers.

Mr. Hendricks was elected an Associate Member of the American Society of Civil Engineers on May 1, 1895, and a Member on April 4, 1911.

EDWIN WESLEY HESS, M. Am. Soc. C. E.[1]

DIED MAY 27, 1938

Edwin Wesley Hess, the son of Harmon and Sarah Hess, was born at Fishing Creek, Pa., on September 5, 1868, on a farm in Columbia County. His ancestors were from the "Rhine Provinces," and his forebears came to America in 1745 to escape the oppression of Frederick the Great. They settled near Bethlehem, Pa., but, in 1790, some of the family moved northward to Columbia County.

Edwin Wesley Hess received a common school education, and attended a country "academy" for one year. After teaching for two terms, he decided to turn to engineering, which had been his ideal since boyhood.

His engineering career was begun in 1887 when he was employed as Rodman by the Louisville and Nashville Railroad Company, near Cumberland Gap, Va. Then followed a series of railroad jobs for the Norfolk and Western Railroad Company; the New York, Ontario and Western Railroad Company; the Pennsylvania Lines West; the Choctaw, Oklahoma and Gulf Railroad Company; and many others. In 1899, he became Assistant Engineer for the New York Central Railroad Company, on the "River Line" east of Clearfield, Pa.

Upon the completion of this work, Mr. Hess opened a general engineering office in Clearfield for private practice, and it was here that he spent most of the remainder of his life. In 1906, after the building of the United Traction Company trolley line between Du Bois and Sykesville, Pa., on which he was Chief Engineer of Construction, he opened a branch office in Du Bois under the management of his brother, Mr. Oliver P. Hess. In both these offices, Mr. Hess built up a complete record of dealings which forms an interesting and authentic chronology of much of the county's history.

Work in these offices has been carried on with as many as twenty-five assistants, and included much of the coal and fire-clay developments of this region, railroads, trolley lines, and land surveys, with some of the operations extending as far as New York, West Virginia, Kentucky, and Tennessee.

---

[1] Memoir compiled from information supplied by the family and from data on file at the Headquarters of the Society.

Paving of streets, and presentation of water supply and dam cases before the State Public Utility Commission were also problems handled by this firm.

In later years, Mr. Hess made the boundary surveys for tracts bought for the State of Pennsylvania by the Forestry Department. He was one of the last of the older men who practiced the art of land surveying.

He was Clearfield County's first Chairman of the County Relief Board established under the Pennsylvania Emergency Relief Board. He was appointed to this position in September, 1932, and served in that capacity for eighteen months.

Mr. Hess was a member of the Presbyterian Church; the Clearfield Lodge of Free Masons, Clearfield Chapter; Williamsport, Pa., Consistory, Jaffa Temple of the Shrine; Fraternity Club of Clearfield; and the Acorn Club of Du Bois. He was a former member of the Rotary Club of Clearfield, Acacia Club of Williamsport, the Pennsylvania Society of New York, the Pennsylvania Forestry Association, and the American Geographical Society. Among the technical Societies, he was a member of the American Water Works Association, the American Institute of Mining and Metallurgical Engineers, The Engineers Society of both Pittsburgh, Pa., and Harrisburg, Pa., and the American Association of Engineers of Chicago, Ill.

As an Engineer, the variety of railroad surveys and construction, the numerous clay and bituminous coal properties and mines with which Mr. Hess had to do, and the municipal work which he planned and executed will attest. As a man his relations with those with whom he came in contact were such as to create many friendships of long standing, and to win for him the respect of all with whom he associated. In his university of " hard knocks," Mr. Hess taught, and proved to be an inspiration to, many a young man in the field of engineering. As a citizen, he developed many ideas for the common good not only of his own community, but of many others.

He was married in 1899 to Maude D. Bouton, who died in 1916. There were no children by this marriage. In 1918, he was married to Bessie M. Rhinard, who survives him, together with their three children, Ruth Marie, Sara Agnes, and John Wesley. Also surviving are four brothers, Bruce W., George W., Robert F., and Oliver P. Hess.

Mr. Hess was elected a Member of the American Society of Civil Engineers on May 7, 1913.

FRAZER CROSWELL HILDER, M. Am. Soc. C. E.[1]

Died September 7, 1937

Frazer Croswell Hilder was born in St. Louis, Mo., on January 16, 1881, the son of Frank Frederick Hilder and Jeanne (Croswell) Hilder.

He received his Grammar School education and his High School training in St. Louis. He was graduated from the University of Missouri, at Columbia, Mo., in 1904 with the degree of Bachelor of Science in Civil Engineering, and, in 1907, he received the degree of Civil Engineer from the same University.

---

[1] Memoir prepared by William S. Anderson, Assoc. M. Am. Soc. C. E.

During his undergraduate days, Mr. Hilder spent his summers with survey parties employed in the Water Department in Washington, D. C. After his graduation he worked as Instrumentman and Draftsman in the District of Columbia Engineering Department from July, 1904, to December, 1905. From January to May, 1906, he was employed as Instructor in charge of Engineering at the Intercontinental Correspondence University, at Washington, D. C. In this connection he also prepared engineering courses and supervised instruction. From June to July, 1906, he served as Instrumentman in charge of sewer construction at Spencer, N. C., for the firm of Pressey and Weller.

Mr. Hilder was with the Chesapeake and Ohio Canal Company as Draftsman in charge of right-of-way mapping from August to September, 1906, after which, until January, 1907, he was engaged as Leveler for the Mississippi River Commission. From February to May, 1907, he served as Surveyor in charge of control survey on the Mexican border with the Southwest Division, United States Army. From June to September, 1907, he was engaged as Leveler, Draftsman, and Topographer on location by the Missouri River and Gulf Railroad Company, after which, until February, 1909, he was again with the Mississippi River Commission, serving as Junior Engineer in charge of levels, Permanent Marks Party, being responsible for two groups engaged on ordinary levels of high accuracy, also tertiary triangulation and base lines.

In March, 1909, Mr. Hilder entered the service of the United States Indian Office, Washington, D. C., as Draftsman in charge of mapping Indian Reservations, and from July, 1910, to September, 1916, he served as Office Engineer in charge of all engineering work of the Service. In this capacity Mr. Hilder had the distinction of having designed the first highway bridge over the Colorado River at Yuma, Ariz. He also acted in advisory capacity for the design of a three-hinged arch bridge over the Colorado River near Needles, Calif. From October, 1916, to April, 1917, he was with the Bureau of Yards and Docks, United States Navy Department, as Design Draftsman on Structural Steel and Concrete Design.

In January, 1917, Mr. Hilder was appointed a Captain of Engineers in the Officers Reserve Corps, and in May of the same year he was assigned to active duty at the Reserve Officers Training Camp, Fort Myer, Virginia. Later, he was transferred to the 317th Engineers, at Camp Sherman, Ohio, and left the United States in December, 1917, for service overseas. He was assigned to duty as Assistant Construction Officer with Headquarters, Base Section No. 3, Line of Communication, American Expeditionary Forces. In April, 1919, he was promoted to the rank of Major (Engineers), and assigned to duties as Construction Officer. He returned to the United States on August 19, 1919, and was mustered out of service on October 31, 1919. He accepted appointment as Major, Engineers Reserve, in March, 1920, and was a very active and valuable member of this organization until his death.

From November, 1919, to September, 1926, Major Hilder was engaged as Supervising Draftsman, Bureau of Yards and Docks, Navy Department, on a wide range of structural design; he investigated possibilities of reinforced concrete for radio towers, and designed deferrization plants for the Naval Air Station, at Pensacola, Fla., and at the Naval Academy, at Annapolis, Md. Later, he was in charge of the design of plants for storage and handling of fuel oil, lubricating oil, and gasoline, including pumping plants and fire protection, notably of the plant at Portsmouth, N. H., costing $1 000 000.

From October, 1926, until his death in September, 1937, he served in the office of the Supervising Architect in the Treasury Department, at Washington, D. C., as Associate Structural Engineer on the structural design of public buildings.

Major Hilder well typified a large number of engineers who devote a lifetime to the service of the Government. He will be remembered by his many friends and associates for his thoughtful and kindly concern for all with whom he came in contact; his devotion to his highest ideals, both in his professional and daily life, was unfailing.

He was a member of the Society of American Military Engineers, the National Reserves Officers Association, and the National Society of Professional Engineers.

He was married on December 7, 1910, to Janie Frost, of Washington, D. C., who, with his two sons, Frazer and Peter, survives him. He was buried with full military honors in Arlington National Cemetery, Virginia.

Mr. Hilder was elected a Junior of the American Society of Civil Engineers on September 6, 1904; an Associate Member on April 30, 1912; and a Member on January 14, 1924.

EDWARD LOVERING INGRAM, M. Am. Soc. C. E.[1]

DIED JULY 25, 1938

Edward Lovering Ingram, for many years Professor of Railroad Engineering and Geodesy in the Civil Engineering Department of the University of Pennsylvania, Philadelphia, Pa., died on July 25, 1938, at his home in Grand View-on-Hudson, N. Y.

Edward Lovering Ingram was born in Philadelphia, on September 9, 1862, the son of John and Ella F. (Guier) Ingram. He received his early education in the public schools of Philadelphia, and in 1885 was graduated from Columbia University, in New York, N. Y., with the degree of Civil Engineer.

He was employed in 1885 by the United States War Department as Assistant Engineer on river and harbor improvement and remained in this work for six years. Mr. Ingram spent the next four years as Assistant Engineer with the United States State Department on an international boundary survey between the United States and Mexico. From 1895 to 1901, he was engaged in private practice. For a part of the year 1901 he was employed by the New York Central and Hudson River Railroad Company, and from 1901 to 1906 he served as Civil Engineering Expert Aid at the New York Navy Yard, in Brooklyn, N. Y.

---

[1] Memoir prepared by Francis P. Witmer, M. Am. Soc. C. E.

In 1906 Mr. Ingram was appointed to the Faculty of the Civil Engineering Department of the University of Pennsylvania, in Philadelphia, and continued in that connection until his retirement in 1932. From 1906 to 1911 he was Assistant Professor of Civil Engineering and from 1911 until his retirement, he was Professor of Railroad Engineering and Geodesy.

Professor Ingram was the author of a book entitled "Geodetic Surveying," published in 1911 by the McGraw-Hill Book Company; and for a number of years he aided the Pennsylvania State Registration Board for Professional Engineers in the conduct of qualifying examinations.

During his twenty-six years on the Faculty of the Civil Engineering Department of the University of Pennsylvania, Professor Ingram administered many important courses, particularly in the fields of Railroad Engineering and Geodesy.

A course in which he took particular interest was the Senior Seminar during which he developed a high degree of enthusiasm on the part of the students. His invariably kindly and courteous personality endeared him to both students and Faculty and his passing is a matter of keen regret.

He was a member of Tau Beta Pi and Sigma Xi Fraternities, the American Association for the Advancement of Science, the American Railway Engineering Association, the Alumni Association of the Schools of Science of Columbia University, and the Alumni Society of the University of Pennsylvania.

Professor Ingram was elected an Associate Member of the American Society of Civil Engineers on September 4, 1895; and a Member on October 12, 1925. Having paid dues as a Corporate Member for thirty-five years, Professor Ingram became a Life Member of the Society on January 1, 1930.

HURLBUT SMITH JACOBY, M. Am. Soc. C. E.[1]

DIED NOVEMBER 16, 1938

Hurlbut Smith Jacoby was born on February 7, 1886, at Memphis, Tenn. He was the second son of Henry S. Jacoby, M. Am. Soc. C. E., and Laura

---

[1] Memoir prepared by a Committee of the Central Ohio Section consisting of J. R. Shank, M. Am. Soc. C. E., as Chairman, and R. B. Jennings and C. V. Youngquist, Assoc. Members, Am. Soc. C. E.

(Saylor) Jacoby. His father is Professor Emeritus of Bridge Engineering of Cornell University, Ithaca, N. Y., and the author of a number of textbooks and papers on structural engineering. His ancestors were among the group of Pennsylvania Germans who settled southeastern Pennsylvania during the middle third of the Eighteenth Century. These people were truly American in spirit, a characteristic which was born of their sense of escape from the devastating horrors of European wars, and which was demonstrated by their activities in providing munitions and sustenance, as well as men, for the American army during the most perilous times of the Revolution.

Mr. Jacoby's early childhood years were spent at Bethlehem, Pa., where his father taught Civil Engineering at Lehigh University from 1886 to 1890. The family then went to Ithaca, where the father continued his teaching at Cornell University. Mr. Jacoby received his early education in the Public Schools at Ithaca, and was graduated from Ithaca High School in 1904. His parents, who had inherited the fervent religiousness of his ancestors, were devout Methodists, and were intensely interested in religious education. He was graduated from Cornell University in 1908 with the degree of Bachelor of Arts, and in 1910 received the degree of Civil Engineer from the same University. For two summers preceding his graduation, Mr. Jacoby worked as a templet maker for the McClintic Marshall Company. When he finished school he continued working for the same company until March, 1913, as Draftsman, Designer, Inspector, and Contract Engineer. During this time he was Inspector on the Panama Canal Lock Gates.

From 1913 to 1915 Mr. Jacoby was Chief Engineer for the newly organized Standard Steel Construction Company of Welland, Ont., Canada. While in this position he designed the power plant for the Canadian Kodak Company at Toronto, Ont., Canada, and the grain elevators for the Harbor Commissioners at Montreal, Que., Canada. After Canada entered the war in 1914, the control of the company passed into other hands, and Mr. Jacoby accepted a position in March, 1915, as Assistant Professor of Structural Engineering at the Pennsylvania State College, State College, Pa.

Although Professor Jacoby and his wife were settling down to a life in academic circles, the call of the building industry was too strong, and he accepted a position as District Engineer with The Austin Company of Cleveland, Ohio, in August, 1915. While in this work he became interested in the idea of standard building designs, originated by Mr. H. K. Ferguson; he developed it and became engineer in charge of this phase of the work of The Austin Company. He became an expert on industrial buildings and designed many large industrial plants, of which one of the most important was the Hooker-Electric-Chemical Company at Niagara Falls, N. Y.

In 1918 Mr. Jacoby joined with H. K. Ferguson in founding the H. K. Ferguson Company, of Cleveland, Engineers and Builders. He became its Secretary and Chief Engineer, which office he held until 1923, when he became Vice-President in Charge of Sales. As Chief Engineer he designed many large industrial plants, including some for the National Cash Register Company, the General Electric Company, and the plant for the Homer-

Laughlin China Company at East Liverpool, Ohio, which was original and outstanding for plants in this industry. This work took him to many parts of the world, including a trip to Germany in 1921. He also went to Mexico where he investigated and reported on the conditions of monumental buildings that were settling.

Mr. Jacoby was a particularly able engineer. He was at all times interested in developing new types of structural design, including early experiments on welded structures. He was engaged in conjunction with H. K. Ferguson in the preparation of a book on the history and development of industrial structures, beginning with the early home craftsmen in England and on the Continent, through the Guild days, and up to the present time. Unfortunately this work was not finished at the time of his death. He was the author of a number of magazine articles on industrial building construction.

In October, 1933, while visiting his mother in Washington, D. C., Mr. Jacoby was discovered by one of the officers of the National Industrial Recovery Act (N. R. A.) and immediately pressed into service as Assistant Administrator in the machinery and allied products division. This position demanded a variety of types of work, among which was the developing of specifications for materials and construction.

He remained with the N. R. A. until January, 1935, when the Ohio State Research Foundation, just being developed, called him to be its first Director. He worked in a preliminary capacity as organizer until the incorporation of the Foundation was announced at the First Annual Conference on Industrial Research in November, 1936, when he officially became Research Director and Secretary.

Mr. Jacoby's background of experience and personality peculiarly fitted him for this task. The broad knowledge of industrial processes and problems which he obtained while working with The Austin Company and the H. K. Ferguson Company, together with his ability to make and retain friends, his energetic and affable presence and good nature, and his sound attitude toward the major problems of life, were apparent to every one with whom he came in contact.

Mr. Jacoby laid the groundwork for a comprehensive program of research to the mutual advantage of the Ohio State University and the industries of Ohio and of the Nation. Co-operative arrangements in existence were extended. Graduate fellowships, full-time research positions, and arrangements for faculty members to direct research, testify to his activities in many departments. The Foundation has suffered a severe loss but his work will go on.

On June 26, 1912, he was married to Emma Betsey Farley of Oneonta, N. Y., who survives him. Their children are Hurlbut Saylor, Mary Vaughn, and Betsey Ann. Both of his parents also survive him.

He was a member of the Engineers' Club of Columbus, Ohio, and of the Faculty Club of Ohio State University.

Mr. Jacoby was elected an Associate Member of the American Society of Civil Engineers on November 3, 1915, and a Member on June 20. 1922.

ALFREDO CARLO JANNI, M. Am. Soc. C. E.[1]

DIED FEBRUARY 26, 1938

Alfredo Carlo Janni was born in Caserta, Italy, on November 2, 1869, of an old Italian family of noble lineage. He bore the title of Count, but preferred not to use it after he became an American citizen. He was graduated from the University of Naples, at Naples, Italy, in 1893, with the degree of Civil Engineer, and remained at the University as Assistant Professor of Steel Construction and Strength of Materials for two years.

He then engaged in professional practice, first as Assistant to the Chief Engineer of "Ferriere Meridionali," in which capacity he designed all bridges and steel structures for the Cairo Awan Railway, in Egypt. He also served as Engineer on the construction of a reinforced concrete building for the Egyptian Museum in Cairo, for the English Government, and as Construction Engineer for Zaafrau Palace for the Khedival Family, in Cairo.

From 1896 to 1899, he was Assistant in the Chief Engineer's Office of D'Alessandro and Company, which Company built the several tunnels on the railroad line from Florence to Bologna, Italy. He worked for the same Company on the first Simplon Tunnel.

Mr. Janni came to the United States in 1904 and his first job was the erection of a distillery for the Southern States Alcohol Manufacturing Company, in New Orleans, La. In 1905, he went to St. Louis, Mo., as Assistant Bridge Engineer for the Southern Railway Company, designing most of the reinforced concrete structures on the French Lick Line.

In 1909, he became Assistant Bridge Engineer for the City of St. Louis, in which capacity he served until October, 1912, designing and supervising the construction of many of the steel and reinforced concrete structures built by the City, including the Carondelet Park Bridge and the Kingshighway Viaduct. The Kingshighway Viaduct was noteworthy at the time as containing the flattest reinforced concrete arches of this size constructed to that date. The three main spans were 140 ft, 170 ft, and 140 ft, and the rise of each was one-tenth the span. Considerable difficulty was encountered in the foundations due to soft clay, and Mr. Janni solved this problem by means of an ingenious reinforced concrete spread footing.

On leaving the service of the City of St. Louis, Mr. Janni entered private practice, and soon, thereafter, moved to New York, N. Y., where he practiced until his death.

In 1915, he won a competition for a monumental reinforced concrete bridge design at Petersburg, Va. In 1918, at the request of the United States Shipping Board, he developed a theory and method of design for reinforced concrete ships which were accepted and used. In 1926, he designed and supervised the construction of the large memorial concrete bridge at Lynchburg, Va.

---

[1] Memoir prepared by Clyde T. Morris, M. Am. Soc. C. E.

Mr. Janni was much interested in the field of theoretical mechanics and introduced many European methods of analysis into the United States. In 1922 he wrote a letter to the Board of Direction of the Society, suggesting that tests be made to verify the theory of elasticity when applied to the design of reinforced concrete arches, especially when supported on elastic piers. This letter resulted in the appointment, by the Board, of the Committee on Concrete and Reinforced Concrete Arches, in May, 1923, and Mr. Janni was made a member of that Committee. He gave freely of his time and energy to the work of the Committee until the completion of its Final Report in November, 1934.[2]

He was the author of numerous articles on structural subjects in the technical press and in the *Proceedings* and *Transactions*[3] of the Society.

On March 2, 1908, he was married to Marie Isabel Willcox, and is survived by his widow and a brother, General Vincenzo Janni.

Mr. Janni was elected a Member of the American Society of Civil Engineers on December 3, 1913.

EDWIN SETON JARRETT, M. Am. Soc. C. E.[1]

DIED DECEMBER 26, 1938

Edwin Seton Jarrett was born in Brooklyn, N. Y., on March 7, 1862. His parents were James M. and Sarah Olivia (Heather) Jarrett. The family moved to Buffalo, N. Y., and Edwin was graduated from the Central High School of Buffalo in 1881.

His further education was interrupted until 1885, when he entered the Rensselaer Polytechnic Institute at Troy, N. Y. He was graduated from that institution in 1889 with the degree of Civil Engineer. This period of his life made a profound impression upon him and its influence is seen throughout his subsequent career.

He began his engineering career in the employ of the late Charles Sooysmith, M. Am. Soc. C. E., a son of General William Sooy Smith, M. Am. Soc. C. E. The latter was largely instrumental in the application, in this country, of the pneumatic method for the construction of substructures for bridges. The son was associated with the father in this work but later established an independent company, and it was this company which first employed Mr. Jarrett and, at the same time, another young engineer, the late Daniel E. Moran, M. Am. Soc. C. E.,[2] with whom he was long associated.

Until nearly the end of the Nineteenth Century there were no tall buildings in New York City. South of Tenth Street, on Manhattan Island, the surface of bed-rock disappears below ground level and lies at greater and greater depths toward the south, down to Duane Street. From that point it rises toward the surface, more or less gradually, until, at the Battery, it again emerges. The rock in this region usually is overlaid, first by a comparatively thin stratum of glacial till, or hardpan, and then by sand of various degrees of fineness. Below the ground-water level, the sand is usually very fine and contains mica scales so that, when not confined, it is very unstable.

---

[2] *Transactions*, Am. Soc. C. E., Vol. 100 (1935), p. 1427.

[3] *Loc. cit.*, Vol. LXXX (1916), p. 1609; also, Vol. 88 (1925), p. 1142.

[1] Memoir prepared by Ralph H. Chambers, Philip W. Henry, and H. C. Baird, Members, Am. Soc. C. E.

[2] *Transactions*, Am. Soc. C. E., Vol. 103 (1938), p. 1840.

The buildings which, up to that time, had been erected in Lower Manhattan, were usually founded on the sand, with footings spread out above the ground-water level. In some cases wooden piles had been used but, except for these, no means had been found to carry excavations down, through the saturated fine sand, to the bed-rock, without danger to adjoining structures.

In 1893, the concentration of business in Lower Manhattan and the rise in the value of real estate made it imperative to increase the height of buildings, and the construction of the Manhattan Life Building at No. 66 Broadway was planned. The architects, Messrs. Francis H. Kimball and George Kramer Thompson, discovered, however, that even by the use of wooden piles, a foundation of sufficient capacity could not be obtained. The area of the lot was not large enough to permit the driving of the required number of piles. The only solution was to reach the bed-rock and this lay 54 ft below the surface.

At this juncture Charles Sooysmith suggested to the architects the use of pneumatic caissons and subsequently built the foundations for this first sky-scraper by this method. Later the Sooysmith Company built, by the pneumatic method, the foundations for the American Surety Building at Broadway and Pine Street, the Washington Life Building at Broadway and Liberty Street, and the Empire Building at Broadway and Rector Street.

It was into this work—the building of bridge foundations and light-houses, the sinking of shafts for coal mines and the construction of the foundations for the Cathedral of St. John the Divine in New York, and the building of deep foundations for buildings in Lower Manhattan—that Mr. Jarrett entered as a young engineer.

In 1898 Charles Sooysmith retired from the construction business and Mr. Jarrett, with some of his associates in the Sooysmith Company, organized the Engineering Contract Company. This company was unfortunate, and in 1900 Mr. Jarrett opened an office in New York as a Consulting Engineer. During this period, he was, for some time, engaged in mining phosphate rock in Florida.

In 1902, with Mr. Franklin Remington and Mr. Moran, Mr. Jarrett organized The Foundation Company. This Company, beginning with very modest financial resources, has completed engineering works in many different countries. It has built the foundations for a great number of the large buildings in Lower Manhattan, among which are the Singer, the United States Realty, the Irving Trust, the J. P. Morgan, the Equitable Trust, the Westinghouse, the Chase Bank, the American Telephone and Telegraph, the Guaranty Trust, the Woolworth, and the Municipal Buildings.

In 1914 Mr. Jarrett resigned from The Foundation Company and, with Ralph H. Chambers, M. Am. Soc. C. E., organized the Jarrett Chambers Company which continued for thirteen years in the construction of foundations and other engineering works, including the foundations for the main office building of the Standard Oil Company of New York at No. 26 Broadway, New York, the shore-protection works at Sandy Hook, the Battle-ship Launching Ways No. 2 at the Brooklyn Navy Yard, the 10 middle launching ways at the Hog Island (Pennsylvania) shipyard, the foundations for the Standard Milling Company Building in Jersey City, N. J., the foundations for the Oswego Elevator of the New York State Barge Canal, and many others.

In his professional work Mr. Jarrett was particularly interested in the construction of mine shafts in soft ground, and 48 such shafts were sunk by companies with which he was associated. He had a firm faith in the final success of the freezing method which was advocated by his first employer, Charles Sooysmith, and which has, of late years, been so successfully employed in the sinking of very deep shafts in northern France, Belgium, and Germany. That it has not come into use in the United States is probably due to the fact that shafts in soft ground, of comparable depths to those sunk in Europe, have not yet been needed here.

Mr. Jarrett's great store of experience, calm judgment, and steadfastness of purpose were always recognized by his associates, and many times he was called upon to assume the entire direction of work which had proved to be particularly difficult. On one of these occasions he spent many months in Montana in the closing of the Hauser Lake Dam. In another, he remained for months in New Orleans, La., on professional work during the yellow-fever epidemic.

Mr. Jarrett's interest in the welfare and development of the Rensselaer Polytechnic Institute and in its students has been lifelong. When he was a student there, he was a member of a students' local society which was founded about 1864 as the Pi Eta Society, but later was changed to the Rensselaer Society of Engineers. Notwithstanding its original name, it was not a Greek letter fraternity, but it came to have a similar function in the student body. It draws its membership from the more earnest and serious-minded of the students. Mr. Jarrett's interest in this society and in its members became, in the last 20 years, one to which he devoted a large part of his time and efforts. In 1923 the late Mr. John M. Lockhart gave a large sum of money to Mr. Jarrett, as trustee, to be used for the building of a house, with living quarters, for the members of this society. Mr. Lockhart was graduated from the Institute, and while he was a student he had been a member of this society. He was graduated two years before Mr. Jarrett, and it is an evidence of the esteem in which Mr. Jarrett was held that this sum was placed in his hands without any specific limitations. The building was planned, built, and furnished under Mr. Jarrett's direction.

Mr. Jarrett's interest in the Institute was not confined to this society alone. In 1924 he was elected an Alumni Trustee of the Institute and served one year, but resigned because of ill health. In December, 1926, he was elected a Life Trustee and served as such until his death. In December, 1931, he was elected a member of the Prudential Committee, the executive committee of the

Trustees, and served until February, 1938. He was also a member of the Finance Committee from November, 1935, until December, 1938.

Because of these several offices, he became thoroughly conversant with the affairs and problems of the Institute. When the President of the Institute, the late Palmer C. Ricketts,[3] Hon. M. Am. Soc. C. E., died, there was no one so thoroughly familiar with them, and in December, 1934, Mr. Jarrett was elected Vice-President, with all the duties of President. He served in this office until September, 1935, when William O. Hotchkiss, M. Am. Soc. C. E., was elected President. Following this, he continued to serve the Institute in an advisory capacity and in charge of the enlargement and reconstruction of its gymnasium building, until within about a year of his death. His conscientiousness, which was one of his outstanding characteristics, was shown in February, 1938, when he insisted that his resignation as Vice-President be accepted because he felt that the state of his health prevented his filling the position properly.

Mr. Jarrett had traveled widely. During one of his vacations, in his student days at the Institute, he made a trip to Australia and around the world. At a later time, he spent one of his vacations in climbing the mountains of Wales. He made several trips to Europe, and in 1926 spent a winter with Mrs. Jarrett on the Island of Majorca. His work carried him many times to many parts of the United States.

The outstanding quality of Mr. Jarrett's character was his high sense of honor in his personal and business relationships. As an instance of this, he repaid, over a period of more than ten years, investments which friends had made and lost in the Engineering Contract Company. These were in no sense loans to him, or to the Company, but were investments in the stock of the Company, made in the belief that it would be successful.

Mr. Jarrett's early school days in Buffalo brought him into an environment which awakened in his mind a love for the use of perfect English, and in his later life his letters and other writings were excellent examples of English composition.

He was fond of people and, particularly, of his many friends in the Century Club of New York. He was ever ready to help younger men, professionally, where a little unsolicited action on his part would further their interests. He was very thoughtful of the welfare of his personal friends, frequently doing favors for them which entailed considerable effort on his part.

Mr. Jarrett was also greatly interested in public affairs, although he never took an active part in politics. He was fond of music and of fishing but not of outdoor games. However, he was fond of country life, and in 1911 he purchased Wild Goose Farm in the Shenandoah Valley, near Shepherdstown, W. Va. The house was very old and he modernized it completely without altering its mellow attractiveness. It was here that his children were brought up, and it remained in his possession until his death.

On June 26, 1909, Mr. Jarrett was married to Cora Hardy of Norfolk, Va., who survives him. He is also survived by his two sons, Edwin Seton, Jr. and William Armstead, and by his daughter, Mrs. Olivia Jarrett Fowler.

---

[3] *Transactions*, Am. Soc. C. E., Vol. 101 (1936), p. 1497.

He was a member of the Louisiana Engineering Society, the Rensselaer Society of Engineers, and St. George's Society; also the University and Century Clubs of New York, the Nassau Club of Princeton, the Cosmos Club of Washington, D. C., and the Engineers Club of London, England.

Mr. Jarrett was elected an Associate Member of the American Society of Civil Engineers on May 1, 1895, and a Member on April 6, 1909.

JENKS BUFFUM JENKINS, M. Am. Soc. C. E.[1]

Died February 1, 1939

Jenks Buffum Jenkins was born at Allegheny, later a part of Pittsburgh, Pa., on January 28, 1869, the son of Friend William and Seloma Wood (Buffum) Jenkins. On the maternal side his American Ancestry ascended through nearly three centuries to the early days of Plymouth Colony. His only brother, Lieut. Friend W. Jenkins, Jr., U. S. Navy, was one of those who perished when the Battle-ship *Maine* was destroyed by explosion in the harbor of Havana, Cuba, on February 15, 1898.

His formal education was begun in the Public Schools of Pittsburgh, and was concluded by a 4-yr engineering course in the Western University of Pennsylvania, later the University of Pittsburgh, from which he was graduated in June, 1888, with the degree of Civil Engineer.

Mr. Jenkins' first practical experience was acquired during the summer vacation of 1887, when he served from June to September as Assistant on the Engineering Corps of Edeburn and Cooper, Civil and Mining Engineers of Pittsburgh. Upon graduation he began his long and useful engineering career in the capacity of assistant in the office of the City Engineer of Allegheny.

His railroad service began on June 24, 1889, when he entered the organization of the Maryland Central Railroad Company, later the Maryland and Pennsylvania Railroad Company. He remained with this company until November 15, 1889, serving as Transitman and Assistant Engineer.

On November 18, 1889, he entered the service of the Baltimore and Ohio Railroad Company as Assistant Engineer, and the association thus begun was continued until March 31, 1893. Within this period he served as Resident Engineer on the construction of the classification yard at Brunswick, Md., made extensive property surveys for the Real Estate Department, and supervised the construction of the Staten Island Terminal and South Beach Extension of the Staten Island Rapid Transit Railway.

His work during the succeeding seven years comprised a wide variety of duties and service in several organizations. From June to August, 1893, he was employed as Structural Steel Draftsman by Riter and Conley, of Pittsburgh; during the succeeding year he served as Topographer for the Baltimore and Washington Traction and Tramway Company, and as Transitman in charge of a party on preliminary and location for the Washington and Great Falls Electric Railway. In July, 1894, he entered private practice in general engineering, including electric railway construction, at Pittsburgh, which he continued until March, 1896. He then entered the Department of Street Improvements, New York, N. Y., as Topographical Draftsman, and, in June, 1898, became Assistant Engineer for the Board of Public Improvements of that municipality, in charge of street openings for the Borough of Queens, in which capacity he remained until May, 1900.

---

[1] Memoir prepared by Philip G. Lang, Jr., M. Am. Soc. C. E.

On May 1, 1900, he re-entered the service of the Baltimore and Ohio Railroad Company, and, with the exception of the World War period, the remainder of his life was devoted to the interests of that Company. Upon appointment he was assigned to responsible charge of the construction of the coal pier at Curtis Bay, Md.; he then, successively, handled the construction of the Crisp Yard at Curtis Bay; line improvements on the Curtis Bay Branch; the sixth Street Bridge at Wilmington, Del.; Jackson Street coal pier, at Philadelphia, Pa.; improvements at Glenwood, Pa.; the development of a low-grade line through the Pittsburgh District; and third and fourth track work between Wheeling Junction and McKeesport, Pa.

Between 1905 and 1914 Mr. Jenkins undertook an extensive program of surveys and studies for improvements and changes on various parts of the Baltimore and Ohio System, and compiled numerous statistical reports embodying the results of his investigations. Although some of these projects were not actually completed, his analysis was, in each case, characterized by extraordinary clarity and wealth of detail, which developed every phase of the subject, and omitted nothing which might be of value in guiding the management to an intelligent decision.

Mr. Jenkins' mental powers were of a keenly analytical character, whether concentrated upon abstract scientific fact or questions of railway economics. Credit is due him for the establishment of rules to govern the use of the railway transition curve and the development of the ten-chord spiral, adopted by the American Railway Engineering Association. In the field of railway organization he has a claim to distinction as the originator of the movement which resulted in making the railroad fiscal year coincident with the calendar year—that is, January 1 to December 31, instead of July 1 to June 30; this arrangement has been productive of vast economic advantages in the allocation of maintenance appropriations.

When, early in 1914, it became necessary to consider the appointment of a properly qualified man to supervise the valuation of the Baltimore and Ohio properties, the diversified experience and peculiar intellectual gifts of Mr. Jenkins marked him as one eminently fitted for this post. Accordingly, on March 1, 1914, he became Valuation Engineer for the Baltimore and Ohio System. The magnitude of this task, and the challenge that it offered, even to Mr. Jenkins' capacity for sustained and intensive research, can be appreciated, in some degree, when it is realized that the Baltimore and Ohio is the world's oldest trunk-line railroad, with a continuous history dating from 1827, and that many priceless records of its earlier days had been destroyed in the great Baltimore fire of 1904, lost, or otherwise dissipated through the vicissitudes of this long period.

During the succeeding four years, Mr. Jenkins applied himself assiduously to the difficult task confronting him. Under his guidance this great and complicated undertaking progressed steadily, and the results of systematic investigation and research began to take definite and intelligible form.

Mr. Jenkins had been a vigorous proponent of the National Defense Act of 1916, by which the Reserve Officers Training Corps was created, and had observed with profound interest the developments of the World War, since its beginning, in August, 1914. As the final crisis of that conflict approached, and the participation of the United States became inevitable, the martial and patriotic tradition of his family asserted itself, although he remained at his post in the Baltimore and Ohio organization until the end of 1917.

Effective January 2, 1918, he obtained a furlough for the purpose of entering the National organization, and was appointed Constructing Quartermaster, in charge of hospital erection, with the rank of Captain. In that capacity he supervised the work on U. S. Hospitals No. 18, Azalea, N. C., No. 12, Biltmore, N. C., No. 19, Waynesville, N. C., and No. 23, Hot Springs, N. C. The nature of Colonel Jenkins' work and responsibilities detained him in the military establishment for several months after the actual conclusion of hostilities. He was honorably discharged from the National service on August 16, 1919, and, two days later, on August 18, 1919, resumed his duties as Valuation Engineer of the Baltimore and Ohio Railroad Company, to the administration of which he devoted the remainder of his life. His major accomplishment during this concluding phase of his career was the completion of the Baltimore and Ohio Railroad valuation, which he pushed with accelerated speed, after the interruption of the war period.

Through these mature and studious years, a portion of his time was devoted to the interests of various patriotic and military organizations, with the special object of maintaining the Nation in a state of readiness to defend its interests. In 1920 he was made Lieutenant Colonel of Engineers, and, three years later, became Colonel of Engineers in the Officers Reserve, which distinction he bore throughout the remainder of his life.

He was a member of the American Railway Engineering Association, for which he served as Chairman of the Track Committee for five years. He also held membership in the Society of American Military Engineers, American Legion, Military Order of the World War, and the Engineers Club of Baltimore, Md.

On March 24, 1897, Mr. Jenkins was married to Margaret Bailey Newman, at Baltimore, who, with two daughters, Mrs. Clyde E. Loose, and Mrs. Gwynn Kenneth Crowther, and a granddaughter, Dean Jenkins Loose, survives him.

Mr. Jenkins was elected a Member of the American Society of Civil Engineers on April 18, 1916.

FRANK WASHBURN JENNINGS, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 28, 1938

Frank Washburn Jennings was born at Logan, Ohio, on March 11, 1868 His parents were William Henry Jennings and Caroline Frances (Allen) Jennings.

His father who was also an engineer and member of the Society began his career on location and construction of the Hocking Valley Railroad, which he later served for twenty-two years in the capacity of Chief Engineer.

His mother, a member of a pioneer family that emigrated from England in the early part of the Seventeenth Century, was a direct descendant of John and Priscilla Alden who crossed on the Mayflower.

Mr. Jennings' family moved from Logan to Columbus, Ohio, when he was five years old, and the greater part of the remainder of his life was spent in this city. He was graduated from Central High School in Columbus in 1886, and attended Ohio State University for two years, leaving to take a position under his father with the Hocking Valley Railroad Company.

The early years of Mr. Jennings' professional life were devoted exclusively to railroad work. He served as Rodman and Transitman for the Hocking Valley, Kanawha and Michigan, and Pittsburgh and Lake Erie Railroad Companies in the period from January, 1885, to January, 1893. After a short period with the Toledo and Ohio Central Railroad Company as Resident Engineer, and with the Kanawha and Michigan Railway Company as Assistant Engineer, he rejoined the engineering staff of the Hocking Valley Railroad Company in the capacity of Assistant Chief Engineer, in charge of preliminary and location surveys, occupying this position from October, 1894, to November, 1897. Following this engagement he served four years as Assistant Chief Engineer for The Columbus Northwestern and the Detroit and Toledo Shore Line Railway Companies, and from 1901 to 1903 he occupied the position of Assistant Chief Engineer of the West Virginia and Kentucky Railroad Company.

In November, 1903, Mr. Jennings left the railroad work to engage in private practice in Columbus. He organized the firm of Jennings and Lindsay, engaging in general engineering and specializing in railroad and municipal engineering and surveying. Later the firm name was changed to Jennings, Lawrence and Lindsay, and subsequently to The Jennings-Lawrence Company. Mr. Jennings held the position of President of this firm until his death.

This firm under Mr. Jennings' leadership became one of the leading engineering organizations of Central Ohio and served as consulting engineers for many towns throughout Ohio, designing and supervising the construction of streets and highways, water-works, water treatment plants, sewer systems, and sewage treatment works.

---

[1] Memoir prepared by a Committee of the Central Ohio Section, consisting of C. W. Ozias and F. D. Stewart, Members, Am Soc. C. E., and R. B. Jennings, Assoc. M. Am. Soc. C. E.

During the later part of Mr. Jennings' life he became well known as an authority on street and highway construction, and was frequently called upon to serve in the capacity of Master Comissioner in litigation relative to highway contracts.

At the time of the trouble on the Mexican border in 1916, Mr. Jennings served as Chief Engineer at Camp Willis at Columbus, and during the World War he was Chief Engineer in charge of surveys at Camp Sherman, located at Chillicothe, Ohio, remaining there until the signing of the Armistice.

On April 28, 1900, he was married to May Bond of Columbus, who survives him. He leaves also three children—Robert B. Jennings, Assoc. M. Am. Soc. C. E., Alice C. (Jennings) Gotter, wife of Robert J. Gotter, and Dr. Frederick A. Jennings—a sister, Mrs. Carl D. Postle, and four granddaughters.

Mr. Jennings was active in a number of engineering and civic organizations. He was a Past-President and member for many years of the Ohio Engineering Society, later the Ohio Society of Professional Engineers. He was also a member of the National Society of Professional Engineers. He was always most active in the affairs of the Central Ohio Section of the American Society of Civil Engineers and was a Past-President of this organization.

Another organization dear to his heart was the Engineers Club of Columbus, of which he, as well as his father, was a Charter Member, and both were Past-Presidents of this organization.

He was affiliated with the Columbus Lions Club, was a member of Sigma Chi Fraternity, and a member of York Lodge, Free and Accepted Masons. He belonged to the Methodist Church.

Mr. Jennings was elected a Member of the American Society of Civil Engineers on April 16, 1918.

FRANCIS DENIS HUBERT LAWLOR, M. Am. Soc. C. E.[1]

DIED JANUARY 25, 1939

Francis Denis Hubert Lawlor was born in St. John, New Brunswick, Canada, on January 30, 1857, a son of James J. and Mary (Ford) Lawlor. His father was a watchmaker and jeweler. Francis attended a Christian Brothers School.

In 1873 he entered the office of the City Engineer in his home town as a student without pay. At that time the English system required students to remain four years without pay. After two years he secured a place on the staff of the Superintending Engineer for the Maritime Provinces of the Department of Public Works in Canada. From 1875 to 1880 he was engaged in the Maritime Provinces on surveys for river and harbor improvements, dredging bars, constructing public piers and breakwaters, surveying St. John Harbor, in the extension of the Intercolonial Railway, later the Canadian

---

[1] Memoir prepared by Edward Bartow, M. Am. Soc. C. E.

National Railway, in the construction of a terminal, and enlargement of St. Peter's Canal and the Negro Town Point Breakwater.

In 1880 Mr. Lawlor came to the United States and secured a position in the engineering department of the Chicago, Burlington and Quincy Railroad Company. He was placed in charge of the first division of the branch line toward Bethany, Mo., under S. R. Ballard. In 1881 he was transferred to Chicago, Ill., where he was engaged in the work of reorganization and extension of the terminal facilities of the Burlington Lines. He supervised the construction of the old union depot which has since been replaced by the present new Union Station.

In February, 1883, Mr. Lawlor was transferred to Burlington, Iowa, and was the first District Engineer of the Iowa Lines. He held this position until December, 1889, when with several other Burlington Route employees, he went to Montevideo, Uruguay, South America, as Assistant Engineer for the "Ferrol Carril del Oeste," to build railroads for the government of that country. Owing to financial difficulties in the Argentine Republic, prior to the panic of 1893 in the United States and the failure of the National Bank of Uruguay, all work was suspended.

After his return to the United States, he made surveys in the Black Hills, S. Dak., for the Burlington Railroad Company, and later entered the contracting firm of Lawlor, Connor and Company, St. John, to build the Tobique Valley Railroad in the northern part of the province. His next position was that of Assistant Engineer on the enlargement of the Galops Canal at Cardinal, Ont., Canada on the St. Lawrence River, about 9 miles below Ogdensburg, N. Y. Later he was transferred to Port Colborne, Ont., the upper end of the Welland Canal, and was in charge of the contract work of the Department of Railways and Canals at that place.

In 1903 Mr. Lawlor accepted the position of Superintendent of the Citizens Water Company in Burlington, a position which he held for thirty-six years, until his death.

He was recognized as one of the outstanding water-works engineers of the upper Mississippi Valley. He was a member of the Illinois Water Supply Association, a life member of the American Water Works Association, and a member of the Canadian Society of Civil Engineers.

He was keenly interested in his profession and was ready at any time to promote experiments and adopt modifications which would improve the operation of his plant and the purity of the product. He regularly attended meetings and conferences of the numerous engineering societies of which he was a member and had an active interest in the Illinois and Missouri Valley sections of the American Water Works Association.

He was married on January 17, 1900, to Lila W. Foote, daughter of Mark S. Foote of Burlington. Mrs. Lawlor died in 1933. One daughter, Mrs. Albert Schulte, formerly Mary Josephine Lawlor, and three grandchildren, Elizabeth Lucile, Carol, and Francis Lawlor Schulte survive. Mr. Lawlor was the last of his family; two sisters, Mother Clara of Montreal, Que., Canada, and Mother Josephine of Boston, Mass., both members of the order of the

Ladies of the Sacred Heart, and a brother, James, of St. John, preceded him in death.

Mr. Lawlor was active in community affairs. He was a member of the Rotary Club, Knights of Columbus, an honorary member of the St. Vincent De Paul Society, and for some years served as a member of the board of trustees of the Free Public Library of Burlington. He is reported by his fellow members to have been just as conscientious in his public work as in handling the business of the water company and his associates on the library board had high commendation for the services he rendered. He was a member of St. Paul Catholic Church.

Mr. Lawlor was elected a Junior of the American Society of Civil Engineers on October 6, 1886, and a Member on March 6, 1895. He was made a life member of the Society in January, 1928.

ALLAN BENJAMIN LEA, M. Am. Soc. C. E.[1]

Died July 17, 1938

Allan Benjamin Lea was born on May 15, 1866, in Buenos Aires, Argentine Republic, the son of Samuel and Margaret Isabella (Rankin) Lea. He received his early education in the public schools of Buenos Aires. At the age of 12, he entered the National University of Buenos Aires and was graduated in 1883. He maintained a high scholastic record and was rated as one of the three leading students in his Class. Later, he returned to the University and received the degree of "Agrimensor" in 1894, and that of Civil Engineer in 1902.

His engineering work was begun in 1884, at the age of 18, in the Drafting-Room of John F. Latrobe Bateman, Engineer, on the sewerage and waterworks system of Buenos Aires. The following year Mr. Lea was made Junior Assistant on construction of the sewerage works.

In March, 1886, Mr. Lea was employed by the Buenos Aires Great Southern Railway Company with which he remained for three years. He spent the first year in the Drafting-Room; the second year making surveys for new stations; and the third year as Leveler and Instrumentman on surveys for new lines.

From December, 1888, to January, 1890, he acted as Chief Assistant to the Resident Engineer on the construction of South of Santa Fé and Cordoba Railway. From January, 1890, to May, 1894, he was Manager and Chief Engineer with the firm of Hopkins, Gardom, and Tetley, Contractors, as follows: January, 1890, to December, 1891, on the construction of a railway line from Belgrano to Las Conchas (a branch of the Buenos Aires and Rosario Railway), including a 140-ft skew bridge over the Central Argentine Railway and a retaining wall a mile long, on the shore of the River Plate; 1892, on the Punta Piedras Division; and 1893, to May, 1894, on the line from Magdalena to Atalaya.

---

[1] Memoir compiled from data on file at the Headquarters of the Society and information supplied by James C. Lea, Esq., Buenos Aires, Argentine Republic.

In November, 1894, he received his degree as "Agrimensor Publico," or Surveyor, in the Province of Buenos Aires, and for the following seven years he was engaged in private practice and in studying for his degree of Civil Engineer which he received in 1902.

From December, 1902, to December, 1906, Mr. Lea was Chief Engineer of a Commission appointed to explore and survey, by triangulation, 12 600 sq miles in Chubut and Rio Negro Territories.

Mr. Lea returned to private practice in 1906, his work including surveys, valuations for Law Courts, and advice on irrigation and drainage work.

Mr. Lea took great interest in the study of mathematics, and was considered one of the leading mathematicians in the Argentine Republic. From childhood he was fond of reading and was thoroughly versed in philosophy, logic, political economy, history, and the Classics. Being endowed with an excellent memory, he could converse freely on all these subjects.

Modest by nature and possessing high moral principles he was much esteemed and beloved by his friends. He was respected by his assistants and workmen for his considerate kindness, altruism, and knowledge, and by his employers for the conscientious and able manner in which he carried out all work entrusted to him.

Mr. Lea was not married. He is survived by three brothers—John S., Norman E., and James C. Lea.

He was a member of the Centro Nacional de Ingenieros, Sociedad Cientifica Argentina, and of the Association of Members of American National Engineering Societies in Argentina. He was the author of several engineering articles published in *La Nacion* and *La Ingenieria.*

Mr. Lea was elected a Member of the American Society of Civil Engineers on March 4, 1908.

JOHN WALTER LEDOUX, M. Am. Soc. C. E.[1]

Died November 7, 1932

John Walter Ledoux, the son of John and Almina (Knox) Ledoux, was born near St. Croix Falls, Wis., on August 28, 1860. His ancestry on his father's side was French-Canadian; on his mother's side, he was of Scotch descent.

His father was a farmer and, later, an explorer in the Lake Superior mining regions, and the boy's earlier education was obtained in the public schools of villages in the Lake Superior District, of Michigan. He worked in the iron mines mines of this District from the age of nine (when his mother died) until he was twenty-one, leaving school at the age of thirteen, upon the death of his father. His duties in this work were connected with engines and boilers and other mine machinery.

---

[1] Memoir prepared from information on file at the Headquarters of the Society.

While working in the mines, his spare time and nights were spent in study and, at the age of twenty-one, he had devised a method of finding the direction of a mine drift; this was practically his first invention. Its success and the recognition of its value in mining operations attracted attention, and led to advice which resulted in Mr. Ledoux preparing for a higher education. For a short time he attended Adams Collegiate Institute, at Adams, N. Y., and in 1883, he entered Lehigh University, at South Bethlehem, Pa., from which he was graduated with honors in 1887, receiving the degree of Civil Engineer.

Technical practice for Mr. Ledoux began during his student days through employment on engineering work at spare times and during vacations. Upon his graduation from Lehigh University, he became Borough Engineer of West Bethlehem, Pa., in order to carry to completion work upon which he had been engaged. This work included a complete survey of the Borough, establishing grades, and setting monuments. Next, he entered the employ of the Stanwix Engineering Company, of Rome, N. Y., of which firm he became a member in 1889, continuing the association until he was appointed Chief Engineer of the American Pipe Company, of Philadelphia, Pa., in 1891. He served in this capacity until 1920 (when the Company's expansion activities practically ended) after which he continued as its Consultant, and entered into private practice as a Consulting Engineer.

The engineering activities of Mr. Ledoux were many and diversified. Although specializing in hydraulics and making investigations and reports on water supply and water-power projects, together with the design of plants and systems, he also invented and manufactured extensive scientific apparatus used in connection with water supply systems and filtration plants for regulation, control, and measurement. He also testified before Public Service Commissions and other tribunals in condemnation proceedings, rate cases, valuations, and other legal matters, and wrote many papers for publication and presentation on such engineering subjects as hydraulics and water supply and treatment, valuations, and rates. Mr. Ledoux visited and studied plants in Europe and in South America. He was among the early investigators on the scientific appraisal of utility properties for valuation and rate-making, on which he was a recognized authority; he was also one of the pioneers and an authority on water treatment and on rapid sand filtration in the United States.

During his career as an engineer, investigations were made of many projects with reports thereon for water supplies and power installations, followed by the construction of some of them. Mr. Ledoux designed and constructed gravity supplies, pumping plants, filter plants, wells, more than 100 dams and reservoirs, pipe lines of all classes, conduits, power plants and transmission lines, electric railways, and gas plants.

While with the Stanwix Engineering Company, he was engaged in water supply investigations, mainly in the Allegheny Mountain regions, measuring stream flow, studying rainfall, and investigating water rights; he also served as Resident Engineer on surveys and the construction of a reservoir at Horse Shoe Curve on the Pennsylvania Railroad, with pipe lines to Altoona, Pa.; he constructed reservoirs and pipe lines for the Westmoreland Water Company, supplying Greensburg, Pa.; and investigated and reported on water supply projects in other localities.

As Chief Engineer of the American Pipe Company (later, the American Pipe and Construction Company), his duties were broad and diversified as the Company was engaged in initiating, financing, constructing, owning, and operating water-works properties, and through a subsidiary, the National Gas and Electric Construction Company, extended its activities to other utilities, such as gas-works, electric plants, and street railways.

Among the water-works designed and constructed by Mr. Ledoux were those for: Paris Mountain Water Company, Greenville, S. C., with a filter plant built in 1891, one of the earliest in the United States; Sumter, S. C.; LaGrange, and Milledgeville, Ga.; Opelika, and Selma, Ala.; Asbury Park, Clayton, Glassboro, Millville, Westfield, and Newbold, in New Jersey; Norfolk, Va.; Waukesha, Wis.; Texarkana, Tex.; Syracuse, and Cortland, N. Y.; Rochester and Lake Ontario Water Company; Buffalo and Niagara Falls Water Company; Depew and Lake Erie Water Company; Western New York Water Company; New York Suburban Water Company; New York Interurban Water Company; and the Springfield Consolidated Water Company for the suburban areas surrounding Philadelphia, Pa. Mr. Ledoux developed the water supply system for the Pennsylvania Railroad Company, supplying trunk and branch lines from Philadelphia to Pittsburgh, Pa., from Philadelphia to New York, N. Y., and from Philadelphia to Baltimore, Md., with developed gravity or pumped supplies at: Christiana Creek, and Winters Run, in Maryland; Octararo Creek, in Maryland and Pennsylvania; Stony Creek, near Dauphin; Powell Creek and Clark Creek, near Duncannon; Wild Cat Creek, near Newport; Licking Creek, near Mifflin; Tipton Run, near Tipton; Bell Creek, near Bellwood; Blair Gap, above Hollidaysburg; the South Fork of the Conemaugh; the North Fork of the Conemaugh; Quemahoning Creek; Salt Lick Creek; Bens Creek; Trout Run; Beaver Run, above Johnstown; Tub Mill Creek, near Bolivar; Sugar Run, near New Florence; and Indian Creek, near Connellsville, all in Pennsylvania. He designed and built this system and operated it for two years before turning it over to the owners; the system also furnishes water to some towns.

Mr. Ledoux designed and constructed plants for the Norfolk Light and Power Company, Norfolk, Va.; the Greenville Light, Power, and Railway Company, Greenville, S. C.; a hydro-electric plant on the Schuylkill River, at Conshohocken, Pa.; and a hydro-electric plant on the Lamoille River, at Fairfax Falls for the City of St. Albans, Vt. The latter was built at the beginning of the Twentieth Century, with transmission at 2 300 volts, which was high at that time. He also made reports for power on the Androscoggin River, at Lewiston, Me., and the Salmon River, near Syracuse, N. Y.; and he handled sixteen power and water rights on the Nine-Mile Creek outlet of Otisco Lake. He reported on rights and power of the Susequehanna River, at Wilkes-Barre, Pa.; above and below Harrisburg, Pa.; at Turkey Hill and at Conowingo. He also reported on the Wallenpaupack Creek, above Hawley; Neshaminy Creek, at Neshaminy Falls; Niaugua River, in Missouri; various streams in Arizona, California, and British Columbia, and the Clarion River and Beaver Creek, in Pennsylvania.

In addition to serving as Chief Engineer for the American Pipe Company many outside engagements were filled for water companies and municipalities including, Norfolk, Pittsburgh, Harrisburg, Lancaster, El Paso, Lehigh Coal and Navigation Company, Clear Springs Water Company, Citizens Water Company, of Scottdale, Bethlehem City Water Company, Bristol, Tenn., Water Company, Washington County Water Company, of Hagerstown, Md., New Castle, Del., Water Company, Camden, N. J., Water Department, Wyoming Valley Water Company, and the Girard Water Company, in Pennsylvania.

In 1920 Mr. Ledoux entered private practice as a Consulting Hydraulic Engineer and continued in this status until his death. Among his engagements during this period were those with the Norfolk County Water Company, Western New York Water Company, City of Jamestown, N. Y., Lehigh Valley Coal Company, Wyoming Valley Water Company, Lehigh Coal and Navigation Company, City of Bethlehem, Pa., Clear Springs Water Company of Pennsylvania, Manheim, Pa., Water Supply Company, Mountain Water Supply Company, City of Philadelphia (as Chairman of a Commission for a future Water Supply), City of Norfolk, Pennsylvania Railroad Company, Long Beach Water Company (arbitration case), Lock Joint Pipe Company, City of Harrisburg, City of Camden, Lehigh Water Company, of Easton, Pa., and others.

He was the organizer of the Simplex Valve and Meter Company for the manufacture under his patents of scientific apparatus used in connection with water supply and other liquids, for measurement and regulation.

Through a long and intensely active career Mr. Ledoux wrote many engineering reports on various subjects for commercial purposes, together with papers presented before technical societies and published in technical journals He had had charge, also, of the design and construction of more than one hundred engineering works. He had received more than forty United States patents for his inventions. The Longstreth Medal of Award of the Franklin Institute was awarded Mr. Ledoux in 1919 for meter inventions for use with Venturi tubes, and, at the time of his death, a second award had been reported on favorably for another invention.

In addition to engineering reports and papers, a number of theses were written and works of fiction composed. He was a student of classical literature and music, and an accomplished violinist. As a student, he had been a member of the college track team and of the first intercollegiate football team of his Alma Mater, and, in later years, he took up gymnasium work and lawn tennis.

He was a member of the American Society of Mechanical Engineers, American Institute of Consulting Engineers, New England Water Works Association, American Water Works Association, Pennsylvania Water Works Association, Franklin Institute, Philadelphia Engineers Club, University Club, and Tau Beta Pi Society.

Although he was enjoying excellent health and perfect mentality at the age of seventy-two, Mr. Ledoux was seriously injured by an automobile while crossing a street on a stormy night, November 6, 1932, at Media, Pa. He died the following morning without regaining consciousness.

He was married to Laura A. Uberroth, of South Bethlehem, Pa., on July 9, 1888, and is survived by his widow, a daughter, Mrs. Stephen Gibbs, a son Leonard K. Ledoux, and a grandson John Walter Ledoux.

Mr. Ledoux was elected a Member of the American Society of Civil Engineers on June 5, 1895.

HENRY READ LEONARD, M. Am. Soc. C. E.[1]

DIED JANUARY 11, 1939

Henry Read Leonard was born in Boston, Mass., on April 13, 1858, the eighth generation in direct descent from James Leonard, who emigrated from Pontypool, England, in 1652, and who founded the first Iron Forge in the New World, at Taunton, Mass.

On March 1, 1874, he entered the employ of the Boston City Engineer's Department, where he was engaged in general construction work and bridge design. He resigned from this position in March, 1883, to become an engineer for Cofrode and Saylor (The Philadelphia Bridge Works), remaining with that firm until 1896. During this time Mr. Leonard was intimately connected with the work of designing and constructing many bridges and other structures for the Pennsylvania Railroad Company. In 1897, he was a member of the firm of Leonard-Foley Construction Company.

During 1899 and 1900, he was engaged by the Southern Railway Company to make a general survey and inspection of all metal bridges on the railroad. From 1900 until March 1, 1902, he was connected with the American Bridge Company as Contracting Engineer.

On March 1, 1902, Mr. Leonard was appointed Engineer of Bridges of the Pennsylvania Railroad Company, and served in this capacity until 1906, when he was made Engineer of Bridges and Buildings. On April 1, 1923, he was appointed to the new position of Chief Engineer of Bridges and Buildings, having jurisdiction over the entire Pennsylvania System. This position he held until his retirement, on May 1, 1928.

During Mr. Leonard's service with the Pennsylvania Railroad Company he built a large number of important structures, of both structural steel and reinforced concrete. He was a tireless worker and very accurate in everything he did. He had a host of friends, and they will long remember his keen wit and remarkable sense of humor. He is survived by his widow, three sons, and two daughters.

Mr. Leonard was an enthusiastic member of the American Society of Civil Engineers, of which he served as Director from 1913 to 1915. He was elected a Member of the Society on April 4, 1894.

---

[1] Memoir prepared by Robert Farnham, M. Am. Soc. C. E.

WASHINGTON IRVING LEX, M. Am. Soc. C. E.[1]

DIED DECEMBER 21, 1938

Washington Irving Lex was born on January 19, 1874, at Philadelphia, Pa., the son of Henry W. and Kate C. Lex. He received his early education in the Public Schools of Philadelphia. In 1896 he was graduated from the Civil Engineering Department of the University of Pennsylvania at Philadelphia, Pa., with the degree of Bachelor of Science in Civil Engineering. Later, in 1925, he received the degree of Civil Engineer from that institution.

After graduation, Mr. Lex was in charge of a party making a field survey of about 200 acres of land on the outskirts of Brooklyn, N. Y. He also prepared plans and specifications, with estimated costs, for the development of this work.

In February, 1897, he entered the employ of the Pencoyd Iron Works at Pencoyd, Pa. He served successively as tracer, detailer, and checker of detail shop drawings for all types of steel bridge and building construction. Among the notable structures on which he worked at this time were the Atbara Bridge over the Nile River in Egypt for the British Government, the Clifton Arch Span over the Niagara River at Niagara Falls, N. Y., and the Land, Title, and Trust Building in Philadelphia.

The American Bridge Company was organized in 1900 and took over the Pencoyd Iron Works. At that time Mr. Lex entered the employ of the American Bridge Company and was with that company continuously until the date of his death. He first served as Squad Foreman, in charge of 50 men in the Pencoyd drawing room. Among the larger contracts that he directed at this time were a series of railroad viaducts for the Uganda Railway Company in Africa for the British Government, a series of railroad bridges for the Chinese and Japanese Governments, and the Senate and House of Representatives Office Buildings at Washington, D. C.

In 1903 Mr. Lex was appointed Assistant Engineer in the Estimating and Designing Department of the Eastern Division of the American Bridge Company at Philadelphia. He was in direct and responsible charge of making designs and estimates for all types of steel railroad and highway bridges.

From 1904 to 1908, he served as Assistant to the Plant Engineer of the Pencoyd Plant of the American Bridge Company in charge of 100 to 150 men in the drawing room. Among the notable contracts which he handled at this time were those for the Boston Elevated Railroad Company, the Subway and Elevated Railway on Market Street in Philadelphia, the Wanamaker Store Building in Philadelphia, the first subway construction with elevated extensions on Broadway, New York, N. Y., the Hudson and Manhattan Terminal Buildings, and the Grand Central Terminal Buildings in New York City.

In 1908, Mr. Lex was transferred to the New York Office of the American Bridge Company, where he was made Assistant Engineer in the Estimating and Designing Department. Here he prepared designs and estimates on all types of bridge and building work.

---

[1] Memoir prepared by William H. Chorlton, M. Am. Soc. C. E.

For the past twenty-five years, Mr. Lex acted as a co-ordinator and "expediter" of work, and for this purpose he was a contact man between the American Bridge Company and the customer. In a number of cases he designed and prepared estimates on the work. In this capacity he would follow a contract through the drawing room, shop, inspection, shipment, and erection. Among the important contracts which he handled in this way were the steel for the third tracking of the Third, Sixth, and Ninth Avenue Elevated structures in New York City, the Elevated Railroad Construction for the East New York and Coney Island Districts, Frankford Elevated Railway in Philadelphia, Subway Construction for the Interborough Rapid Transit Company and the New York Municipal Railway Corporation in New York City, the Delaware River Suspension Bridge between Philadelphia and Camden, N. J., the Broad Street Subway in Philadelphia, the Elverson Building for the Philadelphia Inquirer Company in Philadelphia, and the Richmond Power Station for the Philadelphia Electric Company in Philadelphia.

Mr. Lex was stationed in the Philadelphia Office of the American Bridge Company from 1922 to 1928. With the exception of this time, his headquarters were the New York Office of the company from the year 1908 to the time of his death. He always made his home in Philadelphia and commuted daily between the two cities.

In all his interests he was critically exact and as definitely trustworthy and responsible. He shunned no trust to which he had subscribed any accountability. By these qualities he endeared himself to his friends and associates.

On April 18, 1901, he was married to Inez Estella Apgar of Philadelphia. His widow and three children, Evelyn, W. Irving, Jr. (an electrical engineer), and Dorothea, survive him.

Mr. Lex was a member of, and for the past fifteen years the Treasurer of, the Spring Garden Street Methodist Episcopal Church of Philadelphia. He was a member of several branches of the Masonic Order. He was a registered Professional Engineer in the State of Pennsylvania.

Mr. Lex was elected an Associate Member of the American Society of Civil Engineers on May 2, 1906, and a Member on April 1, 1914.

JOHN MACDONALD, M. Am. Soc. C. E.[1]

DIED JANUARY 28, 1938

John Macdonald was born in Glasgow, Scotland, on October 18, 1878. He was the son of James Macdonald, a builder, and Catherine Macdonald.

---

[1] Memoir prepared by Warren C. Taylor, M. Am. Soc. C. E.

He came to the United States when he was seven years old and lived in New York, N. Y., where he received his education and was graduated from the Woodbridge School, and New York University.

In September, 1895, Mr. Macdonald began his technical career, as an Apprentice for C. T. Wills, Incorporated, of New York City, becoming an Assistant Foreman in 1902. In September of the same year he entered New York University, in New York City, and in June, 1906, received the degree of Bachelor of Science in Civil Engineering.. In college he took an active interest in his Class and was Chairman of the Class Day Committee. During his Junior and Senior years he acted as Instructor in Drawing at the University.

Soon after his graduation, Mr. Macdonald was employed by the Bliss Griffiths Company as Construction Superintendent, which position he held until November, 1908. During the next year, he was Superintendent for Deisler and Stephenson on the construction of large residences. In October, 1909, Mr. Macdonald again joined the staff of C. T. Wills, Incorporated, and served as Construction Superintendent for six years.. He then went with the Thompson-Starrett Company, with which he remained until September, 1924.

His work with these construction companies gave him varied experience in building construction, which included supervision of such buildings as residences for James Speyer, Adolph Lewisohn, and Otto Kahn; the station of the New York, New Haven and Hartford Railroad Company, at New Haven, Conn.; Sterling Laboratory, at Yale University, at New Haven; Steinway Building, in New York City; and the International General Electric Building, at Schenectady, N. Y.

During his residence in New York City Mr. Macdonald found time to be an Instructor in Plan Reading and Estimating at Cooper Union from 1912 to 1915.

He was sought to take charge of the course in Building Construction established by the Thompson Starrett Foundation, at Union College, in Schenectady, and became Assistant Professor of Civil Engineering in 1924. This gave him opportunity to give to the students the benefits of his years of experience in this field of work. He also taught courses in Structural Design. He was Associate Professor from 1927 until his resignation in 1933.

At the time of his death Professor Macdonald was engaged in private engineering, and resided at Dumont, N. J.

He was a patient, energetic worker and a man of sterling character. In his younger days, he took an interest in the activities of the Presbyterian Church, and from 1900 to 1910 was Superintendent of the Sunday School at the Rutgers Presbyterian Church, in New York City.

Professor Macdonald's fraternal interests centered in the Chancellor Walworth Lodge No. 271, F. and A. M., of New York City.

During his residence in New Haven, he was married on January 4, 1922, to Lillian Hargrave, who survives him.

John Macdonald was elected a Member of the American Society of Civil Engineers on April 25, 1932.

FRANCIS CHARLES McMATH, M. Am. Soc. G. E.[1]

DIED FEBRUARY 13, 1938

Francis Charles McMath was born on January 29, 1867, at St. Louis, Mo. He was the son of Robert Emmet and Frances (Brodie) McMath. His father, a distinguished engineer of the past generation and also a Member of the Society,[2] was born in New York State where he attained manhood, but seeking a career farther west, he moved to St. Louis. His mother, until her marriage, lived in Detroit, Mich.

Francis Charles McMath was educated at Washington University, at St. Louis, from which he was graduated in 1887 with the degree of Bachelor of Engineering. Fifty years later, in 1937, Wayne University, at Detroit, conferred on him the Honorary Degree of Doctor of Engineering. In 1931 he was made an Honorary Alumnus of the University of Michigan, at Ann Arbor, Mich.

Following his graduation, Mr. McMath became a Draftsman with the old Detroit Bridge and Iron Works. A year later, he was promoted to the position of Assistant Engineer, and designed many important structures. In another seven years, he was advanced to full responsibility as Chief Engineer. He continued to hold this position until 1900 when he severed his connection with the Company. Although he designed many railway and highway bridges during these years, including the rebuilding of the Victoria Jubilee Bridge, over the St. Lawrence River at Montreal, Que., Canada, this period might well be considered one of preparation for even more important work.

In 1900, together with Willard Pope, M. Am. Soc. C. E., and Mr. B. S. Colburn, Mr. McMath organized the Canadian Bridge Company, Limited, at Walkerville, Ont., Canada. For twenty-one years he was President of this Company, during which time many bridges, both large and small, from the Atlantic to the Pacific, were built for the Grand Trunk, Grand Trunk Pacific, Canadian Pacific, and other Canadian Railway Companies.

In 1911, the St. Lawrence Bridge Company, Limited, of Canada, was organized for the purpose of constructing the cantilever bridge, with a span of 1 800 ft, over the St. Lawrence River near Quebec. Mr. McMath became a Director and Consulting Engineer for the new Company, which was owned jointly by the Canadian Bridge Company, Limited, and the Dominion Bridge Company, of Montreal. The successful completion, in 1918, of this record-making cantilever span was due in no small part to the energy and engineering skill of Mr. McMath. It stands as a symbol of his career.

He was also actively interested in other work. In 1906, for instance, he organized the Essex Terminal Railroad Company, of Walkerville, Ont., serving as its President and Director until 1921. He was also a Director in the Motors Metal Manufacturing Company and the Grosse Isle Bridge Company.

---

[1] Memoir prepared by Willard Pope, M. Am. Soc. C. E., and L. C. Wilcoxen, Assoc. M. Am. Soc. C. E.

[2] *Transactions*, Am. Soc. C. E., Vol. LXXXIII (1919–1920), p. 2268.

As is so often the case with busy men, Mr. McMath found time to devote to civic affairs. In 1920, he became a Trustee of the Detroit Bureau of Governmental Research, a work in which he remained actively interested to the end of his career. He served as President for the years 1926 to 1928, inclusive. The Bureau, which is devoted to improving the City Government, accomplished much during this period. Mr. McMath, having previously served the City as Street Railway Commissioner, gave particular attention to the organization and management of the Detroit Street Railway. He also gave considerable study to the collection and disposal of municipal refuse and the City's sewage disposal problem, as well as many other municipal activities.

He served, too, on the Bell Isle Bridge Commission and the Sewage Disposal Commission. His service with the former resulted in the beautiful multiple-arch bridge which connects Belle Isle to Detroit, while the latter connection is bearing fruit in the construction of a treatment plant.

Mr. McMath's zest for knowledge led him into the realm of astronomy. In order to carry through original researches, he helped to build the McMath-Hulbert Observatory, at Lake Angelus, Michigan (later given to the University of Michigan). He was a member of its staff from 1930 to 1938, and assisted in the production of some remarkable motion pictures of celestial bodies. This work has been recognized by the Franklin Institute, at Philadelphia, Pa. In 1933 he, his son, Robert R. McMath, and Judge Henry S. Hulbert were the joint recipients of the John Price Wetherill Medal awarded by the Institute for "their design and construction of novel apparatus for making motion pictures of astronomical subjects."

In 1890, Mr. McMath was married to Josephine Cook, of Detroit, who died in 1914. The three children of this marriage, Robert R., Niel C., and Marion McMath Edwards, survive him. In 1916, he was married to Madeline Davenport King who also survives him. This was the family about which his life revolved. He was primarily a home-lover, a loyal husband, and a devoted father. They, in turn, furnished him the inspiration for his breadth of living.

Mr. McMath was a Presbyterian and a Republican. He was a member of the Country Club of Detroit, the Detroit Club, Grosse Pointe Club, the University Club (Detroit), and the Engineering Society of Detroit. He was a Fellow Member of the American Association for the Advancement of Science; a member of the American Astronomical Society; Honorary Curator, University of Michigan Observatory (1928–1938); and a Faculty Member of Sigma Xi Fraternity (Michigan Chapter) in 1933. His love of the out-of-doors found expression through his membership in the Huron Mountain Club, and the Turtle Lake Club, an old hunting and fishing club.

It is not easy to pick out the most important of Mr. McMath's many striking characteristics, but certainly a most outstanding one was his absolute and unfailing intellectual integrity. He simply did not know what a dishonest thought was, either toward himself or any one else. He had a way of penetrating almost instantly to the central essence of things, never being led astray by non-essentials, but instinctively discarding them like so much chaff.

The unusual quality of his fine, rare intelligence and power of initiative is shown by his many achievements, not only in the engineering field, but in civic matters, and also of real importance, with the collaboration of his son, in astronomy. These achievements speak for themselves. There was far more to the man than his remarkable mind, however, as his countless friends would testify. He had a rare gift of friendship, never speaking or thinking ill of any one—other than having a righteous scorn for any dishonesty—and accepted people as they are, always seeing the best in them. His never-failing sense of humor was not only a delight to every one with a grain of appreciation, but many times would ease off a tense situation and prevent things from being taken too seriously. He never was over-subtle, but had a certain essential simplicity and directness which was like a breath of fresh air. Beneath all, as a deep undercurrent of his nature, was a high courage and sound optimism, which kept him from admitting defeat until the very last "card had been played," but let him accept the absolute inevitable without the slightest repining.

His zest for life was remarkable and he got the greatest joy and satisfaction not only from his work, but from his play, always being a real lover of the out-of-doors. It is difficult to imagine a finer companion than he was, either as a business associate or as a fellow sportsman, and he lived his life to the full to the very end.

Mr. McMath was elected a Member of the American Society of Civil Engineers on February 25, 1924.

WALTER HUNTLEY MANSFIELD, M. Am. Soc. C. E.[1]

Died September 10, 1938

Walter Huntley Mansfield was born in Camden, Me., on June 28, 1863, the son of Alfred D. and Sophia Josephine Mansfield. His mother was born in London, England. The boy received his education in the public schools of Boston, Mass., and was tutored seven years while at work for the Boston and Providence Railroad Company, under Mr. C. D. Miner, who was Chief Engineer of the railroad.

From 1879 to 1885, Mr. Mansfield acted as Rodman, Instrumentman, and Assistant Engineer on surveys and plans for terminal improvements and double-track work for the Boston and Providence Railroad Company. He then went with the West End Street Railway Company, later, the Boston Elevated Company, as Assistant Roadmaster, and on surveys and general work until 1890. For the next eleven years Mr. Mansfield was a member of the firm of H. Gore and Company, of Boston.

In 1901 he was made Manager of the Boston Asphalt Company and Superintendent of the National Construction Company. This work included the paving of streets, building sewers, etc. Mr. Mansfield was with this firm until 1902 when he went into private practice as an engineering member of Powers and Mansfield Company, of Troy, N. Y. His first work in this capacity was to build and line with concrete the Tomhannock Tunnel for the Troy Water-Works. This firm converted the Au Sable-Keesville Railroad from steam to electricity and also rebuilt the Corning and Painted Post Street Railway, and constructed the Elmira-Corning and Waverly Interurban Railway.

---

[1] Memoir prepared by James M. MacMartin, M. Am. Soc. C. E.

Mr. Mansfield preferred building street railways and he was very successful in this line. He did this type of work in Revere, Malden, Medford, Fall River, and Lowell, Mass.; Pawtucket, R. I.; New Haven, Conn.; Burlington, Vt.; and Plattsburg, and Corning, N. Y. In 1912 Mr. Mansfield and Mr. L. B. Harrison, of New York, N. Y., built seventeen miles of canal in Demarest, N. J.

In 1913, Mr. Mansfield entered the Engineering Department of The Delaware and Hudson Railroad Company and, later, was made Valuation Engineer, remaining in this position until 1921 when he became Engineer for Industrial Development, a position he occupied until his illness in November, 1926, at which time he retired to his farm in Colchester, Vt., where he lived for twelve years. He died there on September 10, 1938. His interest in engineering affairs was maintained until his death.

He is survived by his widow, Frances Rachel (Macrae) Mansfield, and one brother, the Hon. Edward C. Mansfield, of Boston.

He was a member of the Ticket and Freight Association of The Delaware and Hudson Railroad Corporation, the Engineers Club of New York City, the Troy Club, and the Albany Society of Civil Engineers, of which he had served as President in 1923.

Mr. Mansfield was elected a Member of the American Society of Civil Engineers on September 3, 1913.

WALLACE NELSON MAYHEW, M. Am. Soc. C. E.[1]

DIED JANUARY 1, 1939

Wallace Nelson Mayhew was born in Philadelphia, Pa., on March 14, 1880, the son of Wallace and Sadie E. (MacGinley) Mayhew.

His early education was received in the Public Schools of Philadelphia, followed by the Central Manual Training High School. He entered the University of Pennsylvania, at West Philadelphia, Pa., as a member of the Class of 1901, but left in the spring of 1900, in his Junior year, to enter the active practice of structural engineering. He received the degree of Bachelor of Science from the University in 1921 and the degree of Civil Engineer in 1927.

From 1900 to 1902 Mr. Mayhew was actively engaged in structural design. In 1902 he became a partner and Chief Engineer of Stewart and Stevens Iron

---

[1] Memoir prepared by a Committee of the Philadelphia Section consisting of Reginald C. Scott, and Charles A. Howland, Associate Members, Am. Soc. C. E.; and Berthold F. Hastings, M. Am. Soc. C. E .

Works, a steel fabricating firm in Philadelphia. Stewart and Stevens Iron Works merged with and became the Montgomery Iron and Steel Company in 1912, Mr. Mayhew continuing his connection and partnership. At his death he was President and owner of the Montgomery Iron and Steel Company.

In addition to his executive work, he maintained an active contact with the engineering activities of his firm. He also engaged in considerable research work in structural engineering and metallurgy.

Mr. Mayhew was very active in sponsoring legislation of benefit to the construction industry, and it was largely due to his untiring efforts that uniform Bond Laws were passed by the State of Pennsylvania in 1931, and by the Federal Government in 1935. In addition, he was very active in sponsoring "Buy American," particularly with regard to steel.

He served as a Director or an Executive Officer in many organizations, among them being the Structural Steel Board of Trade of Philadelphia, Philadelphia Builders Exchange and Philadelphia Federation of the Construction Industry. He was President of the Northeast Chamber of Commerce.

He is remembered by his friends and associates as a man of unusually broad activities and attainments and a man of great kindness in all his contacts.

Mr. Mayhew was elected a Member of the American Society of Civil Engineers on March 5, 1928.

BRADLEY REVERE METCALF, M. Am. Soc. C. E.[1]

DIED MAY 6, 1936

Bradley Revere Metcalf was born at Elgin, Ill., on August 8, 1884, of English parents, James and Isadora (Chapman) Metcalf. He was educated as a Civil Engineer at the University of California, at Berkeley, Calif., and followed this profession throughout his life.

Mr. Metcalf began his engineering career in 1909, devoting most of his time to construction and to design. He worked, successively, with the City Architect of San Francisco, Calif., on plans; with the Southern Pacific Railway Company on general engineering and revaluation; and with Heller and Wilson, on the construction of a building for use as a temporary City Hall by the City of San Francisco. In 1912, he became Superintendent of Construction for J. E. Krafft and Sons on the Mt. Zion Hospital, in San Francisco. When this job was finished he became Office Engineer and concrete designer for the City of Sacramento, Calif. He then supervised the construction of a four-story concrete building for Heller and Wilson, after which he had direct supervision of Huntington Terrace Bridge over Arroyo Seco, at Pasadena, Calif.

---

[1] Memoir prepared by John C. Park, Assoc. M. Am. Soc. C. E.

In 1914, Mr. Metcalf began work for the Los Angeles, Calif., County Board of Flood Control on the design of a 145-ft dam for Big Tujunga Canyon and remained with this organization, engaged in design, construction, and research, until 1915, at which time he began work on the design of small structures for the Los Angeles County Road Department. In 1916, he became Engineer for the Los Angeles Flood Control District in charge of flood-control measures and dam design. A notable structure which he designed while on this job was the Devil's Gate Dam, a combination of dam and bridge over the Arroyo Seco, at Flint Ridge. In 1917, he went to Bisbee, Ariz., and began work for Cochise County, spending two years in the design and construction of pavements and bridges. He was employed on similar work for the Pima County Highway Department for two years, after an intermission of a year with the Truscon Steel Company.

In 1922, Mr. Metcalf was engaged by the City of Tucson, Ariz., on street improvement plans; and, in 1923, he helped design and construct a large high school building in the same city. In 1924, after designing a reinforced concrete power house for the California Edison Company, he was again employed by the Los Angeles County Flood Control District and was quickly promoted to the position of Senior Engineer in charge of design of storm drains and preliminary plans for dams. He was then made Resident Engineer and had full charge of the construction of the Santa Anita, Sierra Madre, and Big Dalton Dams. Following this engagement, he had joint charge of work at San Gabriel Dam No. 1, where he remained until 1930. At this time, Mr. Metcalf became Senior Designing Engineer for the City of Tucson, and had charge of the construction of the Broadway and Sixth Avenue Subways. On May 1, 1932, he became Assistant City Engineer and on May 1, 1935, he became City Engineer, which position he held at the time of his death.

He enjoyed the confidence and respect of citizens and engineers alike, so that his death occasioned editorial comment. City officials reposed unfailing confidence in his advice and direction. He was noted for his loyalty to his job and to his friends.

Mr. Metcalf was a man of many interests and possessed a well balanced culture. He was a Vestryman of Grace Protestant Episcopal Church, a member of the Masonic Lodge, and a member of Phi Sigma Kappa, the American Association of Engineers, and the Tucson Engineers' Club.

Creation was his forte, also his hobby. He loved design and construction, as witness the many monuments which he left in stone, steel, and concrete. For his own amusement Mr. Metcalf wrote stories and scenarios, some of which were published. In his idle moments he made models, designs, and wrote articles, just for the joy of creating things. He left several unpublished papers. He was an indefatigable worker and student. Another hobby was athletics, and he was an expert tennis player.

He was married to Hazel Gulley on September 24, 1914, and is survived by his widow and a daughter, Jeanne.

Mr. Metcalf was elected a Member of the American Society of Civil Engineers on June 9, 1930.

RALPH MILLIS, M. Am. Soc. C. E.[1]

Died November 11, 1938

Ralph Millis was born in Atlanta, Ga., on August 26, 1894, the son of Col. John Millis, of the U. S. Corps of Engineers, and Mary (Raoul) Millis.

After attending the University School in Cleveland, Ohio, Ralph Millis entered the Massachusetts Institute of Technology, in Boston, Mass., in 1912, graduating with the degree of Bachelor of Science in Civil Engineering in June, 1916. At school he stood high in scholastic ratings and took a prominent part in under-graduate activities, in which his cheerful enthusiasm and willingness to work for causes won him a large circle of lifetime friends.

After graduation, he was employed in sales and acoustical construction by the H. W. Johns-Manville Company in New York, N. Y. He was appointed a Second Lieutenant in the Engineer Section, Officers Reserve Corps, on April 2, 1917, and was assigned to active duty on May 8, 1917. After serving in the training camps at Fort Oglethorpe, Georgia, Belvoir, Virginia, and American University in the District of Columbia, he was assigned on August 27, 1917, to the 306th Engineers at Camp Jackson, South Carolina. Lieutenant Millis was promoted to First Lieutenant on March 29, 1918, and on entering the Corps of Engineers of the Regular Army to rank from July 8, 1918, was later promoted to Captain (temporary) to rank from that date.

On July 30, 1918, he sailed for France, serving with his regiment and at headquarters of the 81st Division in action in the Meuse-Argonne Offensive and in the occupation of the St. Dié Defensive Sector. From April to June, 1919, he served in France and Poland with General Haller's Polish forces. He returned to the United States on July 5, 1919.

After temporary duty in Washington, D. C., and Wilmington, Del., he became a student at the Engineer School, Camp A. A. Humphreys (later Fort Belvoir), Virginia, in October, 1919, graduating the following year. He continued there as an Instructor until August, 1922, except for the period from July to September, 1921, during which time he was detailed to the field artillery school at Camp Knox, Kentucky. On July 1, 1920, he was promoted to the grade of Captain in the Corps of Engineers. From September, 1922, to December, 1923, he was in charge of the Supply Division and later of the lock construction at Wilson Dam in Alabama. Returning to duty with troops in January, 1924, he served until November, 1926, as a Company Commander and Staff Officer with the 2d Engineers at Fort Sam Houston, Texas. In December, 1926, he joined the 11th Engineers in the Canal Zone on garrison and military mapping duties and continued this work until September, 1929.

From November, 1929, to June, 1933, Captain Millis served in Washington, D. C., in the office of the Chief of Engineers in charge of the map reproduction plant at Washington Barracks. His next station was at Fort McIntosh,

---

[1] Memoir prepared by Maj. A. C. Lieber, Jr., Corps of Engrs., U. S. Army, M. Am. Soc. C. E.

Texas, where he served with the 8th Engineers Squadron until April, 1934, with the position of Post Commander for a part of that period. He next served as Assistant to the District Engineer at Savannah, Ga., on river and harbor works until July 5, 1935, when he was appointed District Engineer at Wilmington, N. C. On August 1, 1935, he was promoted to the grade of Major in the Corps of Engineers. In September, 1938, he was transferred to military duty as Instructor of Engineers, New Jersey National Guard, at Teaneck, N. J., where he remained on duty until his death on November 11, 1938.

On June 28, 1930, he was married to Elizabeth Myers, of Atlanta, Ga. They had two daughters, Catherine McDonald, born in 1934, and Elizabeth Manigault, born in 1935. In addition to his wife and children, he is survived by his father, Col. John Millis, M. Am. Soc. C. E., U. S. Army (*Retired*), his mother, Mrs. John Millis, and his brother, Walter Millis.

Major Millis was a member of the Society of American Military Engineers, the Army and Navy Club of Washington, the University Club of New York, Phi Beta Epsilon Fraternity of Massachusetts Institute of Technology, and various civil and social clubs. His diversions included sailing and tennis, in which he maintained a keen interest.

He was a qualified and capable troop commander, staff officer, and engineer. His service was efficient and conscientious, and he possessed the confidence and admiration of his colleagues. The associates of his youth and maturity will long remember the gay spirit and enthusiasm he put into all of his activities, and his untimely death is deeply regretted.

Major Millis was elected a Member of the American Society of Civil Engineers on November 9, 1936.

GEORGE PILLSBURY MORRILL, M. Am. Soc. C. E.[1]

DIED SEPTEMBER 29, 1938

George Pillsbury Morrill was born in Feeding Hills, Mass., on October 27, 1874. He was the son of Julius Abbot Morrill and Sarah Chamberlain (Bell) Morrill, both of whom came from lines of old New England ancestry. He attended the Public Schools at Bellows Falls, Vt., and the Springfield (Mass.) High School, entered Yale University, at New Haven, Conn., where he studied civil engineering, and was graduated from the Sheffield Scientific School of Yale with the degree of Bachelor of Philosophy in the Class of 1897.

He taught school for a year at Gardner, Mass., where he was Assistant Principal of the High School. Then he was employed until 1901 as Chainman, Rodman, and Transitman on cadastral and topographic surveys in the

---

[1] Memoir prepared by Howard E. Hyde and Alexander F. Armstrong, Members, Am. Soc. C. E.

City Engineer's office at Springfield. He was also Junior Engineer on street and sewer construction.

The lure of the Orient, the quest for adventure, and his decided interest in English and literature then induced him to go to the Philippine Islands as a teacher of English. He was among the first teachers sent by the U. S. Government to the Philippines and crossed the Pacific on the U. S. Army Transport *Thomas* in 1901. There he became Superintendent of Schools of the Province of Batangas, Island of Luzon, riding the rough roads and trails of the Province to install, or superintend, its schools. He liked the life, the people, and the beautiful country, but engineering seemed to be in his blood, and he turned to it again, accepting an engineering appointment in Manila, P. I.

From January, 1903, to July, 1907, he served as Instrumentman and later as Assistant Engineer in the office of the City Engineer of Manila. Then he became Engineer in Charge of Construction of dam, head-works, and 42-in. pipe line, near Montalban, Rizal Province, for the new water-supply system of Manila. In those days Manila was a combination of an old, Spanish-type city and of a tropical Oriental city, with all the architectural interest and charm that that implies, and also with all the foul odors and lack of sanitation that were a part of it. A picturesque and historical stone wall of massive proportions, that was some centuries old, and a system of moats, filled with stagnant water which harbored immense snakes, surrounded the oldest portion of the city, known as Intramuras. Tidal lagoons, known as esteros, were used both for drainage and transportation. These meandered in all directions throughout the remainder of the city, and were more than generous with their foul odors, particularly at low tide. Many of the streets were narrow, lacked grading and drainage, and meandered almost as much as the esteros. Under these conditions there was much engineering to be done, and Mr. Morrill undertook his part in the work with vigor and zeal—surveying, mapping, and planning for new street lines, bridges, water and sewer mains, and other city projects.

This was one of the most interesting periods of his life. He made many friends, both American and Filipino, who became greatly attached to him. His young Filipino boy, Quintin Cueto, who attended to his personal wants, looked upon him as a father. It was at this time that Mr. Morrill explored the crater of Taal Volcano on Luzon Island, which was semi-active at the time, and which erupted violently a few years later, causing great loss of life. He traveled in China and Japan and among the southern Islands of the Philippine Archipelago. Perhaps his most adventurous trip was a journey on horseback across a part of the Island of Mindanao. Intermittent fighting was occurring between the Moros of that territory, who had not yet been subdued, and the U. S. Army forces, and army permission to make the trip and an army escort had to be secured for himself and his companions.

In July, 1907, he left the Philippines and spent several months traveling in the Orient, Africa, and Europe, and then returned to the United States.

In December, 1907, Mr. Morrill received an appointment as Engineer in the Department of Public Works, Republic of Cuba. Until December, 1908, he was in charge of work at Santa Clara and Camajuani, in the Province of Santa Clara, making surveys and designs for dams, pipes, and distribution systems for those two cities. From then until December, 1914, he was in charge of the construction of flood diversion works at Sagua la Grande, Santa Clara Province, and also located and constructed 30 km of new highways with culverts and bridges, including the Sitiecito Bridge which had seven 150-ft Pratt trusses.

From January, 1915, to March, 1916, he took postgraduate work at Yale University, taught in the Yale Summer School of Engineering, and served a short engagement with the Westinghouse, Church, Kerr Company on construction of a powder plant in Drummondville, Que., Canada.

From March, 1916, to July, 1931, Mr. Morrill was with the Raymond Concrete Pile Company. For four years he was Engineer and Construction Superintendent on work in various locations in Northeastern United States; for the next four years he was District Manager of the New England Territory; he was then sent to Tokyo, Japan, for a year, as Manager of the Oriental Territory; after that he served for six years as Manager of the Florida Territory, with headquarters at Miami.

From 1932 until his death he represented The American Bitumuls Company in the sale and application of highway products in the State of Connecticut.

In 1916, Mr. Morrill was married to Alice Maude Gray, at Springfield, who, with three children, Janet, Margaret, and George, survives him. Since 1932 he and his family had lived at Westbrook, Conn.

Mr. Morrill had many friends. A fine, honest, upstanding man, he was unusually sincere in his friendships, and all who knew him well loved him. His honesty, loyalty, and belief in fair play, and his humor and wit were outstanding characteristics. He abhorred deceit and insincerity in any form and was always outspoken against injustices of any kind. His generosity and willingness to help a friend in need and his kindliness toward those less fortunate than himself were among his finest traits. He took great pride in being a civil engineer and was a credit to his profession.

He was also well versed in history and literature, had a classical as well as an engineering education, and took a keen interest in educational subjects of any nature. He was a devoted husband and father and his home was very dear to him. His untimely death in an automobile accident at Bridgeport, Conn., on September 29, 1938, cut short a life of much usefulness and many accomplishments, and his passing will be deeply mourned.

He was a member of the The Cuban Society of Engineers, the Boston Society of Civil Engineers, the Royal Society of Arts of England, the American Concrete Institute, the Associated General Contractors of America, and the Connecticut Society of Civil Engineers. He was the President of the Miami Section of the American Society of Civil Engineers while in Florida.

Mr. Morrill was elected an Associate Member of the American Society of Civil Engineers on January 2, 1907, and a Member on June 6, 1911.

HARRISON CURTIS MOWER, M. Am. Soc. C. E.[1]

DIED APRIL 16, 1939

Harrison Curtis Mower was born at Grand Haven, Mich., on December 29, 1874. After attending St. John's Military Academy, at Delafield, Wis., he studied Civil Engineering at the University of Michigan, at Ann Arbor, Mich.

He was commissioned Captain in the Detroit (Mich.) Light Infantry in 1896, but at the outbreak of the Spanish American War, he resigned this commission and enlisted as a Private in the 31st Michigan Volunteers in order to see active service at an earlier date. After serving in Cuba, with promotion to the grade of Sergeant, he was mustered out when hostilities ceased.

He then returned to Civil Engineering practice, and from September, 1899, to March, 1902, was with the Michigan-Lake Superior Power Company, at Sault Ste. Marie, Mich. During the latter part of this engagement, he was in responsible charge of contractor's work Sections 2 and 3 of the canal.

From June, 1902, until June, 1917, he was continuously in the civilian service of the United States Engineer Office, being engaged most of this time as Superintendent or Assistant Engineer. He was also occupied with the design and, later, the construction, of many of the locks and dams constructed on the waterway system of the Black Warrior and Tombigbee rivers in Alabama.

His activities as a civil engineer were climaxed by construction of Lock and Dam No. 17 on the Black Warrior River which was completed in 1915. He personally directed the design, and, later, the construction of this project, which provided a 63-ft lift in two flights, at the time the highest lift lock in the United States, and still one of the outstanding structures of its kind.

When the United States entered the World War he again volunteered his services, and, in June, 1917, was commissioned Captain in the Engineer Reserves. In August of that year he was promoted to the rank of Major, and to that of Lieutenant Colonel in April, 1918. He served in France as executive officer of the 307th Engineers, 82d Division, participating in the Meuse-Argonne offensive, and commanded the regiment for a time during the absence of the then commanding officer (Col. Julian L. Schley, later Gen. Julian L. Schley, Chief of Engineers, U. S. Army, M. Am. Soc. C. E.) on other duty.

Colonel Mower returned to the United States and was discharged in May, 1919. He then engaged in business in Los Angeles, Calif. until his retirement in 1930.

He was assigned as commanding officer to the 349th Engineers in July, 1921, and immediately proceeded with the organization and training of his command. Shortly after this assignment he was promoted to the rank of Colonel, Engineer Reserves. At the training camp held at Fort Scott, California, in 1928, this regiment won first place among the units in attendance.

---

[1] Memoir prepared by the regimental staff of the 349th Engineers, under command of Col. Leroy Foster.

Having brought the regiment to this high state of efficiency, and feeling the need of relief from duty, by his own request he was transferred to the inactive list on February 15, 1930, by Special Orders No. 31, Headquarters First Reserve Area.

Major William H. Lanagan, Corps of Engineers, at the time was unit instructor, and made this comment:

> "Colonel Mower represents the highest type of reserve officer and deserves great credit for the excellent work he has accomplished in building up his Regiment. I am loath to see him go, but he has had this step in mind for several months and feels that it is a necessary one."

On February 25, 1930, Colonel Mower was elected Member Emeritus of the Los Angeles Post, The Society of American Military Engineers, in view of the long service, splendid enthusiasm, and special ability in building up the Reserve Corps in general and the 349th Engineers in particular.

Colonel Mower was a member of the Sons of the Revolution, Society of Colonial Wars, the Ancient and Honorable Artillery of Boston, Mass., and other organizations.

After relinquishing command, Colonel Mower continued to take a deep interest in the regiment. Each year he has presented a saber to the junior officer making the greatest progress in preparing himslf for service in time of emergency. Throughout his career he has displayed qualities of loyalty, friendship, and devotion to the highest ideals of the military service, which have been an inspiration to all officers with whom he has served.

Colonel Mower is survived by his wife, Mrs. Mabel Smith Mower, daughter of Dr. and Mrs. Eugene Smith of Detroit, whom he married in 1901.

Colonel Mower was elected a Member of the American Society of Civil Engineers on July 9, 1912.

RICHARD AUSTIN MYERS, M. Am., Soc. C. E.[1]

Died December 28, 1938

Richard Austin Myers was born at Charlotte, N. C., on April 14, 1884, the eighth of eleven children. It may be said that he inherited all the sterling qualities of his forbears; the Myers of North Carolina, the Moores, Rawlinsons, and Springs of South Carolina.

His father, John Springs Myers, born near York, S. C., was a planter of the old school—loved, admired, and respected for his piety, character, and splendid quality of citizenship. He devoted himself to what would now be called scientific agriculture. Because of the proximity of his property holdings to the fast growing city and his far-sighted vision, he became a pioneer in suburban development of beauty, and the first citizen to set aside tracts of land for park purposes. He was active in church work and city affairs, and served in the State Legislature.

---

[1] Memoir prepared by C. A. Mees, M. Am. Soc. C. E.

His grandfather, Colonel W. R. Myers, served in the Mexican War and as a Captain in the Confederate Army. One of his gifts was ten acres of land in Charlotte for the erection of a school for colored youths, later Johnston C. Smith University.

His mother, Mary (Rawlinson) Myers, had an ancestry of equal distinction. Her father served as aide-de-camp to Governor Pickens of South Carolina through the turbulent years of the Civil War. She was a member of the Colonial Dames and the Daughters of the American Revolution, and was active in the management of St. Peter's Hospital and the Thompson Orphanage.

Since succession to the planters' life of his family had become impracticable because of the changes wrought by time, Richard Austin Myers elected a career as an engineer. After graduation from the Public Schools and attendance at Horner Military School, at Oxford, N. C., he matriculated at the Virginia Polytechnic Institute, at Blacksburg, Va., from which he was graduated with distinction in 1905 with the degree of Bachelor of Science in Civil Engineering. Immediately thereafter he joined the field organization of the Southern Power Company (later the Duke Power Company) which was then engaged in the development of hydro-electric plants on the Catawba River at Great Falls, S. C.

After completion of the second, or Rocky Creek Plant, in the late spring of 1909, this organization was dissolved. On June 1, 1909, Mr. Myers joined the Engineer Corps of the United States Army with headquarters at Charleston, S. C. This organization was at that time making preliminary surveys for the Intra-Coastal Waterway System from Wilmington, N. C., to Savannah, Ga.

From his work as surveyor, he advanced rapidly to full charge of this important undertaking, which, by its very nature, made demands on men that are little realized by those who now pass through this waterway. An infected hand called for the utmost in will power and perseverance for continuous effort in the conduct of such work, and these qualities of character, with which Mr. Myers was so richly endowed, made him stay on the job until he was compelled to seek a furlough on February 10, 1912. He returned to his home in Charlotte for treatment, but on October 2, 1912, he again succumbed to the lure of the work and rejoined the Corps as Junior Engineer in charge of river and harbor improvement, which consisted of dredging for channel alterations through Winyah Bay to Georgetown, S. C.

On January 29, 1913, he was married to Marguerite Springs, of Charlotte, and a year later he resigned from the Corps to return to Charlotte where, in rather leisurely occupation and in the continued search for health, he practiced his profession privately until July, 1916.

Following the disastrous floods of July, 1916, as Resident Engineer for C. A. Mees, M. Am. Soc. C. E., the Consulting Engineer, he agreed to undertake direction of the hurried reconstruction of the dam of the South Carolina Light, Power, and Railways Company on the Broad River of the Carolinas, near Gaffney, S. C. (later absorbed in the Duke Power Company system). An outstanding feature of this undertaking was the construction of a 42-ft coffer-dam in the 225-ft wash-out within a period of forty days. This expedient work enabled the operation of the power plant to be maintained during the period of construction of the new masonry spillway.

After completion of this dam, he retained his connection with Mr. Mees until October, 1918, supervising the construction of steel-tower transmission lines from a hydro-electric plant near Saluda, N. C. into Spartanburg, S. C., for the Manufacturers Power Company of Spartanburg.

On November 20, 1918, Mr. Myers joined the Engineering Staff of the Southeastern Underwriters Association, with headquarters, first in Atlanta, Ga., and later in Charlotte. During this last period of professional practice, he was made Hydraulics Expert in the municipal engineering division, and as such he graded and made recommendations for the improvements in a great number of municipal fire defenses throughout the Southeastern States.

He remained in this position until April 30, 1927, when he resigned, and retired from active practice of his profession to devote his entire time to affairs connected with the management of his realty holdings.

In a letter written to the writer, W. S. Fitzsimons, Assoc. M. Am. Soc. C. E., states:

> "He was a man of sterling character and high attainments as an engineer. It was characteristic of him to devote his abilities unstintingly to bring to a successful conclusion any task that he undertook. His fine personality and willingness to help others endeared him to his many associates in the Engineer Department."

Mr. Myers is survived by his mother, his widow, a son, John Springs (a graduate of Virginia Military Institute in the Class of 1938), a younger son, Brevard Springs, a daughter, Caroline Clarkson, and two sisters, Mrs. George Stephens and Mrs. Harold Dwelle.

Mr. Myers was elected an Associate Member of the American Society of Civil Engineers on November 25, 1919, and a Member on July 12, 1926.

EDWIN JAY NICHOLS, M. Am. Soc C. E.[1]

DIED DECEMBER 11, 1938

Edwin Jay Nichols was born at Clear Lake, Iowa, on February 26, 1858, the son of Edwin Nichols and Elizabeth (Hendrickson) Nichols.

He was graduated from Iowa State College, at Ames, Iowa, receiving the degree of Bachelor of Civil Engineering on November 12, 1884.

In March, 1886, he entered the employ of the Mason City and Fort Dodge Railway Company, serving as Chainman, later as Instrumentman, and finally as Resident Engineer on 40 miles of construction. From December, 1886, to February, 1889, he was Resident Engineer in charge of construction, bridging, track laying, and town site work for the St. Louis, Arkansas and Texas Railway Company. From September, 1889, to January, 1890, he was Assistant City Engineer for Dallas, Tex., having charge of construction of street grading, paving, and sewers built under contract.

---

[1] Memoir prepared by W. S. Hanley, Assoc. M. Am. Soc. C. E.

He was with the St. Louis Southwestern Railway Company as Assistant Engineer and Resident Engineer from January, 1890, to August, 1903.

From 1903 to 1912, Mr. Nichols served in various capacities in the Engineering Departments of the Texas and New Orleans Railroad Company and Galveston, Harrisburg and San Antonio Railroad Company, with the exception of the period from September, 1909, to April, 1910, when he was Superintendent for Horton and Horton, constructing street railways at Houston, Tex. From January, 1912, to August, 1912, he was employed as Division Engineer and Roadmaster on the Stephenville North and South Texas Railway. From August, 1912, he was in continuous employment in various capacities in the Engineering Department of the St. Louis-Southwestern Railway Lines until his retirement on January 16, 1933. His most outstanding work was the relocation of the main line from Mount Pleasant, Tex., to Corsicana, Tex., a distance of 142 miles.

Mr. Nichols was a man of sterling and rugged character and one of the last of the early railroad engineers who helped develop our railroads from the pioneer state. His work always reflected the scrupulous and conscientious effort that he put into it. He took a kindly interest in, and gave encouragement to, the younger engineers with whom he was associated. To give an insight into this man's character—he has been known to get up in the middle of the night, when one of his party was suffering with a cold, and administer to his relief. He never lay down to sleep at night until the last youngster in the location party had retired.

During his retirement, Mr. Nichols traveled extensively and kept up his contacts with his former associates. He remained in good health until a short time before his death from pneumonia. He was laid to rest in Oakwood Cemetery, in Tyler, Tex., on December 13, 1938.

He was married on May 10, 1893, to Mrs. A. J. Phillips at Camden, Ark. Although blessed with no children, his home life was ideally happy. He was very much interested in the cultivation of flowers, which he raised with great success, and which added to the beauty of his home. Mrs. Nichols preceded him in death on June 16, 1935. He was a member of the Baptist Church, and Delta Tau Delta College Fraternity.

Mr. Nichols was elected a Member of the American Society of Civil Engineers on September 2, 1896, receiving a life certificate of membership in October, 1937.

CHARLES HAROLD OLMSTEAD, M. Am. Soc. C. E.[1]

Died February 1, 1939

Charles Harold Olmstead, the son of Charles Wesley and Ella S. (Blanchard) Olmstead, was born at Sandlake, Rensselaer County, N. Y., on September 22, 1891.

---

[1] Memoir prepared by George E. Martin, Assoc. M. Am. Soc. C. E.

He received his early education at Troy, N. Y., and was graduated from Troy High School. He took a competitive examination and was awarded a scholarship at Cornell University, at Ithaca, N. Y. He then attended Cornell University from which he was graduated in 1916 with the degree of Civil Engineer. At Cornell he became a member of Pi Kappa Alpha Fraternity, and retained his active interest in that organization throughout his life. At one time he was the Princeps of the Birmingham District, and was also National Chairman of the Endowment Fund.

After graduation, Mr. Olmstead was a Junior Assistant Engineer with the New York State Highway Department at Buffalo, N. Y. He left that position in August, 1917, to enter the Fort Niagara Military Training Camp. On November 27, 1917, he was commissioned a Second Lieutenant in the Field Artillery and later was transferred to the Air Service. He served the major part of his Army career at Kelly Field, San Antonio, Tex., and Vancouver Barracks, Washington. He was discharged from the Army in December, 1918.

After leaving the Army Mr. Olmstead worked for about six months on highway surveys and design with the Illinois State Highway Department at East St. Louis.

In 1919 he took the civil service examination for employment as an Engineer with the newly organized Tennessee State Highway Department and was at the top of the list of those taking the examination. He joined the Tennessee State Highway Department as Assistant Engineer in June, 1919; in August, 1920, he was promoted to District Engineer, and in 1921 was promoted to Division Engineer in charge of the Nashville Division. He served in this position until 1928. A part of this time Mr. Olmstead was Editor of *Tennessee Highways,* the official publication of the Tennessee Highway Department. During this period Tennessee was establishing a State highway system, and Mr. Olmstead took an active part in solving the early problems of organization, design, construction, and maintenance. Many highway projects serve as monuments to him and commemorate his ability as a highway engineer and executive.

In August, 1928, Mr. Olmstead left the service of the State of Tennessee to accept a position as State Representative of The Barrett Company, with headquarters at Nashville, Tenn. In 1930 he was made District Sales Manager with offices at Birmingham, Ala. He was advanced to the position of Consulting Engineer in 1937, with headquarters at Chicago, Ill., and a year later was transferred to Washington, D. C., in the same capacity. In this work he utilized his highway experience by preparing specifications, writing articles, lecturing to engineering students, and advising engineers on various phases of the use of bituminous materials in highway construction and maintenance.

Mr. Olmstead was married to Agnes I. Demers, at Troy, on June 21, 1916. His widow and two children, Alice E. and Charles Harold, Jr., survive him. He is also survived by his father, Mr. Charles W. Olmstead, a brother, Dr. Albert Olmstead (a professor at the University of Chicago), and a sister, Mrs. Jessie Simmons.

Because of his wide knowledge of a variety of subjects outside of engineering, Mr. Olmstead was an entertaining conversationalist and a delightful companion. He was deeply interested in his family and was a devoted husband and father. He had a host of friends inside and outside the engineering fraternity.

Mr. Olmstead was elected an Associate Member of the American Society of Civil Engineers on November 21, 1921, and a Member on April 13, 1936.

JOHN EDWIN OSTRANDER, M. Am. Soc. C. E.[1]

Died October 19, 1938

John Edwin Ostrander was born in Slingerlands, N. Y., on March 20, 1865, the son of John and Catherine (Van Den Bergh) Ostrander. He was graduated from Union College at Schenectady, N. Y., in 1886, with both the degrees of Bachelor of Arts and Civil Engineer. He was one of the Honor Students of his Class. In 1889 he was awarded the degree of Master of Arts by his Alma Mater.

His first engineering work was with the town of West Troy, N. Y., as Levelman on sewer construction. Later the same year he became associated with the New York State Survey as a computer. During 1887 he was first associated with the Chicago, St. Paul and Kansas City Railroad Company as Assistant on Construction, and then as Draftsman for the Phoenix Bridge Company.

Mr. Ostrander's next professional work was with the Engineering Department of the New York State Canals. He was in charge of the lengthening of Locks Nos. 60 and 61 on the Erie Canal. Later he made studies for, and supervised the construction of, the water supply for Clinton Prison at Dannemora, N. Y. In 1889 he was engaged in construction of locks at Amsterdam and Fort Hunter, and later at Rotterdam Junction and Mohawk, all in New York State. In 1890 he was in charge of a field party engaged in making surveys for the improvement of the Champlain Canal. He also worked on the final estimates for the Hudson River improvement.

After these varied and interesting experiences in engineering practice, which were to serve him in good stead in later years, Mr. Ostrander accepted an appointment as Instructor in Civil Engineering at Lehigh University, Bethlehem, Pa., in September, 1891. There he worked under the late Mansfield Merriman, M. Am. Soc. C. E., from whom he apparently received his inspiration to continue in the teaching profession.

During the summer of 1892 Mr. Ostrander was Engineer in charge of construction for L. M. Loss, contractor for the substructure of the railroad bridge across the Mississippi River at Alton, Ill.

In October, 1892, Mr. Ostrander began a five-year period as Professor of Civil Engineering and Mechanical Arts at the University of Idaho, Moscow, Idaho. Professor Ostrander was the first instructor engaged by the University. In this position he organized the Civil and Mining Engineering Departments. He also had charge of construction of the main University building. Professor Ostrander also served as Irrigation Engineer for the Experiment Station at the University, and made surveys and reported on irrigation projects for sub-stations at Idaho Falls and Nampa, in Idaho.

---

[1] Memoir prepared by George A. Marston, Jun. Am. Soc. C. E.

In July, 1897, Professor Ostrander was appointed Professor of Mathematics and Civil Engineering at the Massachusetts Agricultural College, later the Massachusetts State College, at Amherst, Mass. At the same time he took over the duties of Meteorologist for the Experiment Station at the College. As Professor Ostrander used to tell, during the first month of his new duties Mother Nature celebrated his appointment by establishing a new monthly July rainfall record at Amherst.

As head of the Department of Mathematics and Civil Engineering at Massachusetts State College, Professor Ostrander saw many generations of students sit before him. Exacting as a man of science, practical as an engineer, "Johnny O," as he was affectionately known to his students, was an interesting and sympathetic teacher. He was a good judge of character, both of his students and of his colleagues.

Professor Ostrander served as Acting Professor of Astronomy at Amherst College during 1900, 1901, and 1907. He designed and supervised the construction of the sewerage system at Sunderland, Mass., during 1902 and 1903. He contributed to Johnson's Encyclopedia during 1893 and to Webster's New International Dictionary in 1907. He had been a member of the Society for the Promotion of Engineering Education, the Mathematics Teachers of New England, Phi Kappa Phi honorary scholastic fraternity, the Holland Society of New York, and the American Institute of Mining and Metallurgical Engineers, and was also a Mason.

In 1928 Professor Ostrander gave up his duties as Meteorologist at the College and in 1935 he retired from active teaching, having completed thirty-eight years of continuous work at the Massachusetts State College. He was appointed Professor Emeritus of Mathematics upon his retirement.

He was married to Sarah C. Cowan of Youngstown, N. Y., on September 26, 1888. He is survived by his widow; a son, Commander John E. Ostrander, Jr., U. S. Navy; and a daughter, Mrs. Milton Colvin.

Professor Ostrander was elected a Junior of the American Society of Civil Engineers on May 2, 1888; an Associate Member on September 2, 1891; and a Member on April 4, 1905.

JOHN NELSON OSTROM, M. Am. Soc. C. E.[1]

Died January 30, 1938

John Nelson Ostrom was born in Corinth, N. Y., on June 6, 1851, the son of Thomas Legitt and Louisa (Pope) Ostrom. It is interesting to note that Mr. Ostrom's father was born before George Washington's first inauguration and was ten years and nine months old when George Washington died. In 1856, the family moved to East Randolph, N. Y., and it was here that John attended school. Following his graduation from Chamberlain Institute in Randolph he won a scholarship from Cornell University at Ithaca, N. Y., which he attended from 1873 to 1876. He was an exceptional athlete and famous oarsman, being a member of crew from 1873 to 1874, and Captain, Coach, and Stroke in 1875 and 1876, as well as a member of other athletic teams.

---

[1] Memoir prepared by G. A. Haggander, Assistant Chf. Engr., C. B. & Q. R. R. Co., Chicago, Ill.

After completing his course at Cornell he secured employment with the Detroit Bridge and Iron Works, and in 1882 he took a position with the Chicago, Burlington and Quincy Railroad Company.

From 1886 to 1888 he directed the building of bridges on the Gulf Colorado and Santa Fe Railroad in Oklahoma and Texas, later part of the Atchison, Topeka and Santa Fe Railway. The following year he established his own office, specializing in inspection of bridges and serving as Consulting Engineer. For many years he was Consulting Bridge Engineer of the Chicago, Burlington and Quincy Railroad Company. He first maintained an Office in New York, N. Y., then in Pittsburgh, Pa., and about 1915 opened an office in Chicago, Ill., which he maintained until 1932 when he returned to East Randolph to live.

Mr. Ostrom specialized in shop and mill inspection of steel bridges and handled this work on many notable structures, including the Beaver Bridge, at Beaver, Pa., the bridge over the Ohio River, at Metropolis, Ill., and the Chicago, Burlington, and Quincy Railroad Bridge over the Missouri River at Kansas City, Mo. He also made frequent inspections of the Eads and Merchants bridges of the Terminal Railroad Association of St. Louis, Mo., spanning the Mississippi River, and supervised repair work on these structures. One of his last large inspection jobs was that on the Wabash Railway Bridge over the Missouri River at St. Charles, Mo., which has since been replaced.

Mr. Ostrom was very fond of outdoor sports and also kept an active interest in them. His wife, Caroline Deming Ostrom, whom he married in 1903, died in 1913. Mr. Ostrom is survived by a son, John N. Ostrom, Jr.

He was a member of the Western Society of Engineers, and Sons of the Revolution, the East Randolph Methodist Church, and he donated the Ostrom Memorial Building.

Mr. Ostrom was elected a Member of the American Society of Civil Engineers on November 5, 1890.

CHARLES PENROSE PERKINS, M. Am. Soc. C. E.[1]

Died August 19, 1934

Charles Penrose Perkins was born in Philadelphia, Pa., on October 2, 1844, the son of Abraham R. and Margaret R. (Penrose) Perkins. At an age early even for modern times, he entered the University of Pennsylvania, then at its old location on Ninth Street, Philadelphia, and took the collegiate course, including the classics. Graduating in 1863 with the degree of Bachelor of Arts, he entered the Rensselaer Polytechnic Institute, Troy, N. Y., for a course in technical instruction, and received the degree of Master of Arts in 1866.

---

[1] Memoir prepared by Charles P. Keith, Esq., Philadelphia, Pa.

Mr. Perkins began his work at the Bessemer Steel Plant, of Winslow, Griswold, and Holly, at Wyandotte, Mich. There, he remained about a year. With the exception of this first position and his superintendency of the McHaffie Steel Casting Company, at Lamokin, near Chester, Pa., he spent twenty-six years in the service of the Pennsylvania Railroad Company and its Affiliated Companies.

Beginning as Assistant Engineer on the location and construction of the Queen Anne and Kent Railroad and its branch connection with the Delaware Railroad, he was advanced, in 1869, to the position of Assistant in the Office of the Resident Engineer and was engaged on maintenance of way on the Middle Division of the Pennsylvania Railroad. Moving then to the Western Pennsylvania Division, Mr. Perkins was made Assistant Engineer and, later, held the same position on the Pittsburgh Division. In 1873 and 1874, he was engaged on the construction of the Pennsylvania Railroad Station, in Jersey City, N. J. For the next ten years he was, successively, Assistant Engineer in charge of maintenance of way on the Elmira and Canandaigua Divisions of the Northern Central Railroad and the Philadelphia and Erie Railroad. In 1894, he was appointed Assistant to the Real Estate Agent of the Pennsylvania Railroad System east of Pittsburgh, Pa., and moved to Philadelphia. He remained in this work until his resignation in 1892.

Mr. Perkins was a member of the Historical Society of Pennsylvania, the Genealogical Society, Society of Colonial Wars, Art Club, Merion Cricket Club, and a Manager of Hahnemann Hospital and, for years, served as its Treasurer. An Episcopalian, Mr. Perkins was a Vestryman of the Church of the Good Shepherd, at Rosemont, Pa., where he died in his ninetieth year.

On November 13, 1878, he was married to Helen Armstrong Wright, the daughter of Col. John A. Wright. They had three children, Emma M., Rowan Penrose, and Mary Hathorn. His wife and children died before him.

Mr. Perkins was elected a Junior of the American Society of Civil Engineers on February 3, 1875, and a Member on April 5, 1882.

CHARLES STOCKTON POPE, M. Am. Soc. C. E.[1]

DIED MARCH 16, 1938

Charles Stockton Pope was born in Fort Stockton, Texas, on August 10, 1874, the son of Benjamin Franklin and Sara Lee (Poston) Pope. He came of an interesting and accomplished family. His father served as a Surgeon in the United States Army during the Civil War; later, as Chief of the Pension Bureau; Chief Medical Officer in the Santiago Campaign of the

---

[1] Memoir prepared by a Committee of the Sacramento Section, consisting of E. N. Bryan, Thomas E. Stanton, Jr., Fred J. Grumm, and Albert Givan, Members, Am. Soc. C. E.

Spanish-American War; and as Surgeon General of the Philippine Islands. One brother—Saxton T. Pope—was Instructor in Surgery at the University of California, at Berkeley, Calif., and was rated as one of the greatest surgeons of his time in the United States.

Charles Stockton Pope received his early education in Army, private, and public schools. He was graduated in 1897 from Stanford University, at Stanford University, Calif., with the degree of Bachelor of Arts in Civil Engineering. He was a member of the Chi Psi Fraternity, and served on the University track team in 1896 and 1897. In the second semester of his Senior year, he was elected Perpetual Class President.

Immediately after his graduation, Mr. Pope went to work as a laborer on bridge repairs on the lines of the Southern Pacific Railroad Company. During the following two years, he was engaged as Chainman, Rodman, Water Gager, and Sub-Foreman on irrigation surveys and ditch work.

In 1900, he entered the employ of the Standard Electric Company, making surveys for power lines, power-houses, and dams; and in the following year he was engaged in the construction of these facilities. Mr. Pope was engaged in similar work in 1903, after having spent the previous year on the construction of ferry slips and power-houses for the North Shore Railroad Company.

Following a year as a Mine Surveyor in Arizona, Mr. Pope entered private practice in Los Angeles, Calif., in 1905, working on land surveys and on the breakwater, at Venice, Calif. From 1907 to 1915, he was employed by the City of Los Angeles, rising from Surveyor on all classes of municipal work to Assistant Engineer in charge of pavement construction, and, finally, to Highway Engineer in charge of all construction except sanitary sewers and bridges.

His experience in street work led to his acceptance of employment with Warren Brothers Company in 1916 for which Company he acted as District Engineer of California and Nevada, on consulting and promotional work on roads and streets, until 1921. This specialization in street work, particularly of the asphaltic type, furnished the basis for his later achievements in advancing the design and quality of pavements.

The State Highway Department of California was fortunate to secure the services of Mr. Pope in 1922, because of his large, practical experience with asphalt pavements and his knowledge of the California asphalts. For three years he had direct charge of asphalt work on the State Highway System and was appointed Construction Engineer for the Department in 1924, supervising all construction work except bridges. During the years, 1924 to 1928, he was also in charge of the Testing and Research Laboratory of the State Division of Highways. He continued in his capacity as Construction Engineer until his death.

Mr. Pope's contributions to improved practice on highway construction were numerous. He was primarily responsible for the development of the improved asphalt concrete specifications used in California. He developed and patented certain details of the process of machine finishing of asphaltic pavements. His research and studies led to improved Portland cement concrete design. He did much in developing and promoting soil studies and investigation as they apply to highway work.

Technical papers and discussions written by Mr. Pope were many, and appeared in various publications, or were presented at engineering conferences, meetings, and conventions. He prepared a brief and was Chief Reporter on Bituminous Roads at the International Road Congress, held at Milan, Italy, in August, 1926.

Mr. Pope was a member of the Project Committee on Distortion of Concrete Pavements, Highway Research Board, American Association of State Highway Officials Committee on Road Design, American Road Builders Association, and American Asphalt Association. At one time he was a Director of the California Museum Association; a member of the Engineers and Architects Club of Southern California, American Association of Engineers, and the Engineers Club of San Francisco. Membership in fraternal and social organizations included: Sacramento Lodge No. 40 F. and A. M.; Isaac Davis Lodge of Perfection; Masonic Luncheon Club; Sutter Club of Sacramento, Calif., and Del Paso Country Club.

Unfailing courtesy, dignified cordiality, tolerance, generosity, and kindliness were Charles Stockton Pope's marked characteristics. He created and maintained cordial relations with hundreds of contractors with whom he came in contact in his work. His keen sense of humor helped him to maintain a constantly cheerful aspect and behavior. An analytical mind, firmness, and rare judgment made his counsel and advice valuable and sought after. These fine qualities and his lovable nature endeared him to his many friends and associates. He was always, and under all circumstances, a gentleman in the truest and best sense of the word. He rendered distinguished service to the Engineering Profession, ever striving for the higher and finer ideals and by his own example inspiring his brother engineers toward achieving such higher standards. Charles Stockton Pope was a highway engineer. It can fittingly be said of him that: " He always traveled the upper road."

He was married in San Francisco, Calif., on September 19, 1903, to Marian S. Holden, of that city, a painter and etcher of note. She and his two sons, Charles St. George and Paul Francis Pope, survive him.

Mr. Pope was elected a Member of the American Society of Civil Engineers on October 1, 1913. He was a Charter Member of the Sacramento Section of the Society and its third President.

HENRY WITBECK POTTER, M. Am. Soc. C. E.[1]

Died October 9, 1938

Henry Witbeck Potter was born at Whitehall, N. Y., on August 26, 1859, the third son of the Hon. Joseph Potter (Judge of the State Court of Appeals) and Catherine (Eights-Boies) Potter. He received his early education in the public schools of his native town, and later, at the age of seventeen, he entered Rensselaer Polytechnic Institute, at Troy, N. Y., from which he was graduated in 1879.

---

[1] Memoir prepared from data supplied by the family and on file at the Headquarters of the Society.

In August, 1879, Mr. Potter received his first engineering position as Rodman on surveys of the Buffalo, Bradford and Pittsburgh Extension Railroad. Shortly afterward, he was made Assistant Engineer on the same surveys under the late Oliver Weldon Barnes, M. Am. Soc. C. E., as Chief Engineer. He remained in this position until September 1, 1880, when the work was finished.

In November, 1880, Mr. Potter went to Mexico as Assistant Engineer for the Construction Company that built the Mexican National Railway, and remained in this position until November, 1881. From this time until January, 1883, he was in charge of a subdivision of the same road.

In May, 1883, he entered the service of the Trojès Mining and Smelting Company as Engineer in charge of tunnels and surveys of mines. He left this position in March, 1884, and became Chief Engineer of the firm of Bowes Scott Read, Campbell and Company, Engineers and Contractors of London, England, and City of Mexico, D. F., Mexico. In this position, he assisted in such important works as the Drainage Canal in the Valley of Mexico and the pumping plant at Chapultepec, Mexico.

In 1892, he had charge of the Cerro Colorado Mines, in the State of Chihuahua, Mexico, and when these mines were closed, he went to Guatemala where he had charge of the electric light plant and system of telephones, at Quezaltenango. In 1898, Mr. Potter received an offer from the Westinghouse Electric and Manufacturing Company of a position in its Spanish-American Department. He accepted this offer and traveled extensively through South America and Central America, until 1905, when he was sent to Torreon, Durango, Mexico, to open a Northern Branch Office. Shortly afterward the Westinghouse Company went into the hands of a Receiver, and Mr. Potter was called to New York, N. Y. However, he resigned from the Westinghouse Company and accepted a position as Assistant Manager of the Tlahualilo Agricultural Company, in the State of Durango, Mexico, and remained in this position until ill health necessitated his retirement in 1936.

Mr. Potter was a member (Veteran) of the New York Athletic Club, Camera Club of New York, Rensselaer Polytechnic Alumni Association, Troy, N. Y., and Mexican Pilgrim Society.

He was married on September 29, 1891, to Jennie P. Pratt, of New York City, who survives him.

Mr. Potter was elected a Member of the American Society of Civil Engineers on December 5, 1888.

SAMUEL R. PROBASCO, M. Am. Soc. C. E.[1]

Died January 19, 1910

Samuel R. Probasco was born in the City of New York, N. Y., on September 13, 1833, and died at his home in the City of Burlington, N. J.

---

[1] Information for memoir furnished by Theodore Belzner, Affiliate, Am. Soc. C. E. (from Municipal Engineers of the City of New York, 1910).

Mr. Probasco was educated in the Public Schools of his native city. In 1854, during the California gold fever, he went to San Francisco, Calif., by way of Cape Horn. While there he became a member of the Second Vigilance Committee.

In 1856 he left San Francisco and returned to New York and took up the study of engineering. Mr. Probasco worked on the construction of the old Albany Bridge, under the late Julius Walker Adams, Hon. M. Am. Soc. C. E. Subsequently, from 1871 to 1875, he was Principal Assistant Engineer on the Water Board of the City of Brooklyn. At this time he was in charge of the construction of the Storage Reservoir at Hempstead, L. I. and as Deputy was in charge of all details of the work on the water-shed. He was also in charge of the paving and repaving, and for some time was in charge of sewer construction in Brooklyn.

In 1868 Mr. Probasco made preliminary surveys for the New York and Brooklyn Bridge across the East River and in 1875 he became one of the Assistant Engineers for that Bridge. Mr. Probasco remained with the Department of Bridges, the successor to The Trustees of the New York and Brooklyn Bridge, until the time of his death.

In 1898, after the consolidation of New York City and the City of Brooklyn, Mr. Probasco was appointed Chief Engineer of the Department by the Commissioner of Bridges, and he remained in that position until 1901 when he resigned and was transferred to the New York and Brooklyn Bridge. He was appointed one of the Consulting Engineers by the Bridge Commissioner, the late Gustav Lindenthal, Hon. M. Am. Soc. C. E., during 1902 and 1903.

While associated with the Brooklyn Water Works Mr. Probasco invented the modern process of casting curved specials for water pipe.

In 1858 he was married to Anna M. Phillips, of Lumberton, N. J. They had two children, Selden R. Probasco, an engineer, and Samuel K. Probasco, a lawyer.

Mr. Probasco was a member of The Municipal Engineers of the City of New York, The Brooklyn Club, and the Long Island Historical Society, of which he was one of the regents.

He contributed a paper to the Society entitled "An Account of the Operation of the Gunpowder Pile-Driver"[2] which was published in *Transactions*.

Mr. Probasco was elected a Member of the American Society of Civil Engineers on November 18, 1868.

ROBERT REIMANN, M. Am. Soc. C. E.[1]

DIED APRIL 12, 1938

Robert Reimann, the son of Louis Albert Hansen and Christiane Euphrosyne Eugenie Reimann-Hansen, was born in Copenhagen, Denmark, on September 28, 1881. He was christened Robert Louis Reimann-Hansen, but shortly after coming to America, he elected to drop the more cumbersome double name and thereafter used the shorter name of Robert Reimann.

---

[2] *Transactions*, Am. Soc. C. E. Vol. II (1874), p. 403.

[1] Memoir prepared by H. O. Arnurius, Field Engr., The B. & O. R.R., and D. W. Fry, Assoc. M. Am. Soc. C. E.

Mr. Reimann's father, Louis Albert Hansen, was one of the leading wholesale merchants of Copenhagen. His maternal grandfather, Arnold Eugen Reimann, filled a prominent place in Copenhagen's business and civil life and was a co-founder of Handelsbank. A grand uncle, Frederick Jacobsen, was the first to analyze cryolite in Greenland, spending the winter of 1858–59 there. He also was the first to manufacture cement in Denmark and his work in developing a better formula was considered notable at his time.

During his youth Mr. Reimann lived in the old part of Copenhagen bordering on the harbor and opposite the Royal Christiansborg Castle. Here the dignified residences and the state buildings stand side by side overlooking the picturesque waters of that port, while near-by is the cultural center of the city.

Robert Reimann attended the Gammelholms Preparatory Latin and High School from which he was graduated with distinction in September, 1899. He then attended the University of Copenhagen for four and one-half years where he took courses in Philosophy and Engineering, and was graduated with honors in January, 1904, with the degree of Civil Engineer. His formal education was supplemented by courses in languages with a private tutor, under whose guidance he became an accomplished linguist, writing and speaking Danish, French, German, and English, as well as having a thorough knowledge of Latin. In later life, he mastered Spanish and Italian. Following his graduation he rounded out his education by extensive travel in Europe.

Mr. Reimann came to the United States in April, 1904. In view of his travels abroad, his impressions of the splendor of the New York of 1904 are of interest. An excerpt from his notes reads:

> "My first impression of the skyscrapers was, that they are among the most beautiful buildings in the world. * * * Such a magnificent row of houses as line Fifth Avenue can hardly be found elsewhere. Adjacent is the vast Central Park. * * * Fine carriages in never ending rows file by, especially on Sundays, the one more elegant than the other; there are all types of carriages, often drawn by four horses, with coachman and footmen. And there are fine bridle paths, which are much used. Even those who walk are much more elegantly dressed than in Europe."

In May, 1904, Mr. Reimann secured a position as Draftsman under the late Francis Lee Stuart, Past-President and Hon. M. Am. Soc. C. E., then Engineer of Surveys of the Baltimore and Ohio Railroad Company. Mr. Reimann's first assignment was at Cumberland, Md., under the late Harry R. Talcott, M. Am. Soc. C. E., and, later, at the same place under G. D. Brooke, M. Am. Soc. C. E., who is now (1938) President of the Chesapeake and Ohio Railway Company. Both of these men left memoranda of the young engineer's brilliance and of his quick mastery of the principles of railway engineering.

In 1907 Mr. Reimann secured a leave of absence and traveled in Europe for several months, returning in September of the same year to re-enter the

Surveys Department of the Baltimore and Ohio Railroad Company. From that time until February, 1908, he served as Transitman; and from then until October, 1910, as Draftsman in charge of the field office of the Assistant Engineer. During the latter period, Mr. Reimann made studies to determine the location of the revision of line and reduction of grade on the Cumberland Division in West Virginia between Blaser and West End, which included the present double-track Kingwood Tunnel having a length of 4 202 ft.

In October, 1910, he was transferred to the Headquarters Office in Baltimore where he made his home for the remainder of his life. He was assigned as Head Draftsman in charge of office work for the Surveys Department. Serving in this capacity until July, 1915, he had charge of making studies of the improvements proposed on the Baltimore and Ohio Railroad. Of special interest were his studies and determination of the location for the Magnolia Cut-Off, which is east of Cumberland, Md., in the Potomac River Valley, where the river is deeply entrenched on a meandering course through the eastern front of the Allegheny Mountains. The cut-off is 13.2 miles in length, has four tunnels aggregating 6 958 ft, two crossings of the Potomac River, eliminates a helper grade, and effects a saving of 5.7 miles in main-line distance.

A notable part of his work was the exceptionally clear and accurate maps made under his direction. In many cases the maps not only served the immediate purpose for which they were made, but have continued to be used for general purposes. Also, during this period, Mr. Reimann prepared a very comprehensive set of tables for estimating, arranged in such a clear and concise form that they have been in wide use on the Baltimore and Ohio Railroad ever since.

From July, 1915, to the end of his service with the Baltimore and Ohio Railroad Company in May, 1932, Mr. Reimann was Assistant Engineer in charge of surveys, supervising the work of the office force and field parties. The surveys and studies made under his supervision embraced a wide variety of projects, ranging from minor improvements to the proposed reconstruction of major parts of an entire Division, including proposed extensions of the line.

He had a broad grasp of the factors involved in the proposed improvements and with it the ability to plan and conduct his work in an orderly and competent manner. Whenever possible the surveys and studies made under his supervision were carried to a conclusion and the results were recorded and reported in a concise and logical manner so that the merits of the projects could readily be considered at any time.

The general features of a number of his studies were written as separate professional papers and are of lasting value. As an illustration, after making a survey to determine whether an uncontaminated supply of water could be obtained in a coal territory, Mr. Reimann prepared a paper describing the general manner in which the problem was solved. The paper was printed in the *Railway Age* on July 23, 1920. In connection with surveys to determine the liability for flood damage, he made an investigation of stream flow and prepared an outline of a general method of procedure based upon the determination of back-water curves. Also, in connection with his work, Mr.

Reimann made an investigation of several types of retaining walls, bridge abutments, and arch culverts, and, on the basis of the Coulomb theory, prepared an outline of a simple graphic method of procedure for investigating these structures when required for special conditions.

In handling the men under his supervision, Mr. Reimann maintained a firm policy, tempered with impartial justice. He expected of each man a high character, a keen mind, and good work. He felt very strongly his obligation to reward the meritorious worker with further opportunity to develop, and was markedly successful in training his men and in fostering in them a high degree of pride and interest in their work. In return, he derived a very real pleasure from their development and was accorded their high esteem.

Although Mr. Reimann's primary interest was engineering, he also had an intense interest in many subjects outside his profession. As a young man, he studied music and obtained a good general knowledge of the art, as well as becoming a proficient pianist. In later life, he seldom played, but retained a genuine love of music and regularly attended the concerts and the opera. Among a wide circle of musical friends in Baltimore his judgment of music was held in high regard. He was a student of classical literature and was especially interested in, and had a deep insight into, the past civilizations.

On Saturday evenings he held open house for a group of young intellectual friends who were encouraged to participate in discussions covering a wide range of topics. He thoroughly enjoyed the stimulation of their interest, and, being a man of strong personality and decided convictions, he dearly loved and encouraged a spirited argument. These evenings at home, where the events of the past and present, and where their significance with respect to history and to present-day happenings, were discussed, were probably among the most enjoyable occasions of Mr. Reimann's life and are treasured memories among his friends.

During the last twenty years of his life Mr. Reimann traveled extensively, visiting all parts of the United States, every country of Western Europe, and parts of Canada, Mexico, and Africa. It was characteristic that his desire for first-hand knowledge of other civilizations, past and present, was insatiable. Throughout his life he was an assiduous student, keeping fresh the knowledge he had gained and constantly adding to it. Prior to each of his journeys, he carefully planned an unhurried schedule and adhered to it. His were pleasure trips, but with a mind eager to perceive and an industry that impelled him to make clear and concise notes of all his important travels. His notes have been bound and have been enjoyed by his friends, but have never been published.

Mr. Reimann was an accomplished engineer and a cultured gentleman—an extremely interesting companion to his friends and a kind and just preceptor to his subordinates.

He is survived by his widow, Sarah Genevieve (Becker) Reimann, residing in Baltimore, and by two brothers, Albert Reimann-Hansen, Captain Carsten Reimann-Hansen, and a sister, Mrs. Nanna Grønlund, all residing in Denmark.

He was a member of the American Railway Engineering Association; and the Charcoal Club, the Edgar Allan Poe Society, the Engineers Club, the Maryland Academy of Science, and the University Club, all of Baltimore.

Mr. Reimann was elected a Junior of the American Society of Civil Engineers on October 3, 1905; an Associate Member, on February 4, 1913; and a Member on April 17, 1918.

JAMES HERBERT RICHARDSON, M. Am. Soc. C. E.[1]

Died September 1, 1936

Whether it was in the calculation of intricate earthquake stresses or in the detailing of important and involved layouts James Herbert Richardson always acted on the principle that deeds speak louder than words, that an engineer should be seen and not heard and that when he is seen he should be hard at work. He lived out these precepts efficiently and with an equipoise that was an example to others. His associates (and the writer was one of these) have missed him greatly; individually we have at divers times paid tribute to his cherished memory in short periods of silence. During his life he was fairly difficult really to know; but once he became your friend he was a friend completely for life; perhaps that is the reason his memory lingers.

Mr. Richardson was born October 3, 1876, at Lawrence, Mass. Thus, at the date of his death, he lacked a month of being 60 years old. His early schooling was obtained at Lawrence until he was 14 years of age, when he entered High School at Newtonville, Mass. His father was a master car builder and was in charge of the shops at Lawrence. James Herbert was the youngest of seven children, Brother Will being the oldest—twenty-two years older than Herbert. His sister Lucy was nine years older. The four other children died in infancy; and their four little graves at Andover, Mass., were always affectionately tended to by Herbert. Indeed these graves were a point of pilgrimage later when he and his wife were on their honeymoon. His mother died when Herbert was eight years old; thus he became the affectionate "apple of his father's eye"; and the boy had the complete run of the shops at Lawrence. At an early age he developed those traits of acceptance of responsibility and other engineering characteristics which he learned at his father's elbow and which later in his career made him invaluable as a checker and as an independent thinker. He was meticulous in his verification no matter who had been over the ground before. His father had become a noted pool player; therefore, in his later years it was but natural for Herbert to develop a fondness for billiards and pool. He inherited his father's keen eyesight and never had to wear glasses.

From September, 1895, to June, 1900, Mr. Richardson was a student of civil engineering and hydraulics at the Massachusetts Institute of Technology, at Boston, Mass., after which he received a certificate of honorable dismissal in 1900, having completed 150 semester hours of the 160 required for graduation. During his college course, he attended the Institute summer school in surveying, geodesy, stream-flow measurement, topography, and geology. During one summer vacation he was employed as Transitman in charge of party by the Massachusetts Harbor and Land Commissioner on surveys giving line and grade for street construction, drainage and granite block paving of new streets of South Boston. Along with his engineering, as a side hobby, Mr. Richardson took many related courses in biology. Probably he had a yearning to be a physician, but under the influence of his brother Will he turned wholeheartedly to civil engineering.

---

[1] Memoir prepared by Thomas K. A. Hendrick, Assoc. M. Am. Soc. C. E.

From 1900 to 1902, Mr. Richardson was employed by the Eastern Bridge and Structural Company of Worcester, Mass. For this company, he designed, estimated, and detailed structural steel, masonry and timber; and he inspected steel work in the shop and field. This work included railroad and highway bridges, industrial, store, and loft buildings, heavy girders and trusses, and coal handling machinery and other mechanisms.

From 1902 to 1909, Mr. Richardson was employed by the American Bridge Company of New York at East Berlin, Conn., where he designed, estimated, and detailed a great variety of structures including railroad and highway bridges. In 1903, this plant office was closed and Mr. Richardson was one of the few engineers transferred to the design and estimating offices in New York, N. Y., where his duties were similar to those at East Berlin but included checking. In 1905, he was transferred to the office of O. E. Hovey, Hon. M. Am. Soc. C. E., where he designed and estimated heavier steel structures. He designed, detailed, and checked steel work on the Belmont Park Grand Stand, the New York Central Power-Houses at Port Morris, N. Y., and Yonkers, N. Y. He also worked on locomotive turntables. Much of his work was for foreign countries and involved familiarity with foreign specifications.

On November 4, 1904, at Orange, N. J., Mr. Richardson was married to Doctor Anna Mann, a graduate physician, daughter of the Rev. Charles H. Mann, minister of the Swedenborgian Church.

As a young couple, Mr. Richardson and his wife were keenly interested in the work of their church. In later years, they grew to feel that they could better express their religion outside of the organized church. When he was first introduced to his future wife, Mr. Richardson was in the act of placating a small child and this sympathetic understanding of children remained with him throughout his life. Mr. and Mrs. Richardson had two sons, David and Charles Holbrook, both of whom were graduated from The Engineering School of the University of Cincinnati, at Cincinnati, Ohio. Doctor Richardson was college physician at Smith College, Northampton, Mass., for eleven years; and from her home at Gateway House, son David was married to Marjorie Kendall, a California girl. Son Charles Holbrook married Virginia Henkel, a Cincinnati girl. David's sons are David Kendall and Gunnar Drake; Charles' sons are John Henkel and Philip Clark. To his sons, Mr. Richardson always maintained that stimulation of a steady, quiet enthusiasm that kept him perennially youthful in spirit.

In 1909, Mr. Richardson went to the Erie Railroad, Department of Bridges and Buildings, in New York City, where he designed the passenger tunnel and underground station beneath the Erie Railroad tracks at Jersey City, N. J. This work was below the North River water level and for that reason entailed difficult foundation problems; but the work was accomplished without delay to train traffic in the terminal station. He investigated the stresses in many existing railroad bridges and trestles—both steel and timber—under increased loading conditions caused by modern locomotives. He also designed new railroad and highway bridges and viaducts as well as the reinforced arches over Bergen Hill cut.

During the period 1910–1916, Mr. Richardson served with the Boston and Albany Railroad Company in Boston. For them he checked, for litigation, the reinforced concrete of the new Worcester passenger station which was an "all reinforced concrete building." He designed, detailed and checked, and was in charge of the work in the office and field on the Worcester Grade Crossing Elimination. He supervised the construction in the field and did the shop inspection on an important steel two-hinged arch. He solved many difficult foundation problems in the designing of heavy girder, truss and arch bridges, retaining walls, and abutments. During his tenure with the Boston and Albany Bridge Department about 150 spans were installed of which Mr. Richardson was given the most interesting structures to design such as steel arches, concrete arches, and special skew bridge work. Practically all of these spans were erected in a manner to avoid delays in train schedules. Many of the bridges were three-track or four-track structures; on some the old bridge was rolled out and the new one rolled in simultaneously. Besides supervising the actual construction of work that he had already designed, on frequent trips to the work of installation Mr. Richardson often made the necessary surveys for changes required in track alignment, grade and curvature.

Upon leaving the Boston and Albany Railroad Company, Mr. Richardson was engaged by Ford, Bacon and Davis, Engineers, of New York City, during the time that this firm was making an appraisal of the Rhode Island Company's properties from their offices in Providence, R. I. The properties consisted of about 400 miles of traction lines, most of which were electric trolley lines although some of the mileage was steam with the usual power plants, repair shops, bridges, and trestles. Mr. Richardson was in charge of party, had the use of a special car, and reported on all structural work including a drawbridge and large city bridges.

In 1917 Mr. Richardson was given a leave of absence from the firm of Ford, Bacon and Davis to accept a commission as Captain, Engineer-Officers Reserve Corps, in which he served for about two years with the American Expeditionary Forces in France. Upon his return to the United States and his honorable discharge from the U. S. Army, Captain Richardson returned to the firm of Ford, Bacon and Davis for whom he designed and estimated the steel and masonry for the Cheswick, Pa., plant of the Duquesne Power and Light Company and checked the water-work masonry and foundations. He also designed the structures for a briquet plant for coal on the Carolina, Clinchfield and Ohio Railroad.

During the period of 1920 to 1923, Mr. Richardson was employed by Perin and Marshall, McClellan and Junkersfield, and the Central Railroad Company of New Jersey on special problems.

In 1923 and 1924, Mr. Richardson served the firm of Westcott and Mapes, Engineers, of New Haven, Conn., for whom he designed and detailed supports for steam turbo-generators, condensers, and other power plant equipment. He designed various extensions to existing power plants and parts of the new Bridgeport plant of the United Illuminating Company. This work included steel supports for brick chimneys, boiler supports, coal handling machinery, gate houses, and bulkheads on the water-front. He designed a boiler house for the New Haven Gas Company. He designed and checked a reinforced concrete storage warehouse for storing paper which presented difficult foundation problems. In this work, he controlled field operations by means of frequent trips to the site.

During part of 1924, Mr. Richardson was employed by the Foundation Company of New York to design bridges, culverts, trestles and locomotive repair shops for a proposed railroad yard of the Southern Railway Company.

During the period 1924 to 1927, Mr. Richardson joined the forces constructing the Holland Tunnel for which organization he was appointed Assistant Engineer on August 20, 1924. He checked the design of the floor in the tubes and did detail work on the inner lining of the tubes and shafts in which there was a great amount of intricate steel and concrete work. His work also consisted of designing and laying out details of the ventilating buildings which housed the fans and electrical equipment, including piping, air-ducts and conduit system and in checking the detail and shop drawings. He also worked on the "final estimate" until August, 1927, at which time he was recommended to the Board of Water Supply, City of New York, by the then Chief Engineer of the Holland Tunnel, Ole Singstad, M. Am. Soc. C. E.

On November 1, 1927, Mr. Richardson was appointed Assistant Engineer Designer, Board of Water Supply, City of New York, and started to work for that well-known organization. For a short time his work consisted of the design of reinforced concrete on valve chambers and of steel trusses for the support of the ordinary chambers, City Tunnel No. 2. He was with the Board of Water Supply until April 15, 1934. After his initial work, his time was spent on the design and detail work of the drainage shaft No. 9A, its upper and lower chambers, and the masonry and structural steel building which are carried on the upper chamber walls and trusses. This work involved forces of great magnitude and the many studies, layouts, and working drawings bearing the initials "J. H. R." attest the enormous amount of work, ability, and industry of Mr. Richardson. He was in charge of a squad of engineers and draftsmen.

From March, 1935, to May, 1935, Mr. Richardson served with the Department of Parks, New York City, on the Henry Hudson Bridge project, Project No. 16 of the Temporary (State) Emergency Relief Administration. As of May 21, 1935, he was transferred to the Works Division of the Emergency Relief Bureau, City of New York, for work on reports in the Engineering Section. From February, 1936, to August 31, 1936, he served with the Department of Sanitation on the Tallman's Island Sewage Project during which period he was stricken with the illness (appendicitis) to which eventually he succumbed. Mr. Richardson was scheduled to return to the Board of Water Supply to resume his important work for that body on the day that he died, September 1, 1936.

Mr. Richardson's hobbies besides pool and billiards were walking and photography. He had a large album of pictures and snapshots of bridges and locomotives. On a trip to Europe in 1900, he took many pictures of European bridges and engineering works. Although he was not particularly athletic, he was fond of swimming and hiking. At one time, he was a member of the Appalachian Club and enjoyed long walks. Also he liked to study, scientifically, systems of diet, trying them out and adapting his own variations. He particularly delighted in his sons' accomplishments during their college careers. It was a never-ending pleasure for him to describe David's exploit in setting up the firm of " David Richardson—Dogfish." David had an establishment at Bailey Island, Me., for procuring dogfish. He injected the dogfish with colored gelatine and sold them to the biology laboratories of colleges and universities.

Mr. Richardson was a member of the Technology Club of New York and participated actively in its recreational and social programs. On account of his skill at pool and billiards, he won many prizes and tournaments; but he seemed to take more delight in explaining difficult shots to the younger members. He was always ready to help younger members with that kindly advice born of wide experience. The members of the club attest his princely character as a friend and counselor particularly to the younger members as told to the writer by the senior member, Dr. James Duff; and Arthur Hamilton, one of the younger members. In every way he had the cordial regard of his fellow-members and was much beloved for his colorful personality. Without exception, all admired him for his clean living and his confidence as a friend. At any time, he would demonstrate his willingness to go out of his way to do a helpful turn or perform a kindly act for a member. Slow to get acquainted with, once a member knew him, the breadth and depth of his friendship more than compensated for an apparent initial indifference. His friendship conscientiously and steadfastly given was the key to the charm of his personality.

Mr. Richardson at one time was a member of the American Railway Engineering Association and of the American Concrete Institute. He was a licensed Professional Engineer of the State of New York.

Mr. Richardson was elected an Associate Member of the American Society of Civil Engineers on January 2, 1907, and a Member on February 10, 1930.

WILLIAM JACKSON ROBERTS, M. Am. Soc. C. E.[1]

DIED APRIL 6, 1938

William Jackson Roberts was born in the Caroline Islands (an extensive group in the Pacific Ocean east of the Philippine Islands), on May 13, 1860, the son of Ephraim P. and Myra (Farrington) Roberts, Congregational Missionaries. In 1861, his parents resolved to carry on their missionary work in the United States. They landed in San Francisco, Calif., where they took the old sailing vessel, *Jane A. Falkenburg,* for Portland, Ore., reaching there on November 9, 1861. The next spring they moved to White Salmon, in Washington Territory, an early settlement on the Columbia River, where they remained for three years. In 1865, they located permanently at The Dalles, Ore., then one of the most thriving frontier posts.

---

[1] Memoir prepared by Harold J. Doolittle, M. Am. Soc. C. E.

Mr. Roberts received his early education in the pioneer schools of those days. He was prepared for college, however, by his father and mother. His father was a graduate of Williams College, at Williamstown, Mass., and devoted to the Classics. This part of his son's preparation he took upon himself. From his mother, Mr. Roberts received his very thorough training in basic mathematics. In 1886, he was graduated from the University of Oregon, at Eugene, Ore., with the degree of Bachelor of Arts. In 1891 he received his degree of Bachelor of Science in Civil Engineering at the Massachusetts Institute of Technology, at Boston, Mass. Subsequently, he received his degree as Master of Arts from the University of Oregon.

Mr. Roberts began his engineering work in Portland, Ore., being employed on topographic surveys for that city. He soon became Engineer for the Hood River (Oregon) Irrigation Company and thus began a life-long interest in hydraulic engineering. In 1892, he was appointed the first City Engineer at Colfax, Wash. Then, in 1895, he turned his attention to teaching. For thirteen years he was Associate Professor of Mathematics and Civil Engineering at the State College of Washington, Pullman, Wash. During those years more than 1 300 young men came under his influence and training. Mr. Roberts gave tirelessly of his time and experience to "his boys," as he always called them, holding up by precept and example ideals of thorough scholarship and integrity of character, without which, he held, no man can become a real engineer.

During those thirteen years, Mr. Roberts served as Consulting Engineer for many cities and districts in the Pacific Northwest, interesting himself especially in water supplies for municipalities and irrigation projects. For ten years of this period he served on the Washington State Board of Health. He was also instrumental in organizing the Pullman Building and Loan Association, which was one of the first institutions of its kind in the State of Washington.

In 1908, Mr. Roberts decided to devote his entire time to private practice. His first project was to build a modern water system for Medford, Ore., the second in size in the State. In 1911, he was appointed State Highway Commissioner for the State of Washington by Governor M. E. Hay. He laid out and established the primary highway system for the entire State, which was one of his major contributions during his term of office. In December, 1913, Mr. Roberts returned to his field of greatest interest—hydraulic engineering. King and Pierce Counties, in Washington, were confronted with a serious flood-control problem. Under a joint agreement, they formed the Inter-County River Improvement, with headquarters in Tacoma, and Mr. Roberts became Chief Engineer. During the next nine years he directed the expenditure of $2 000 000, straightening, widening, and deepening the Puyallup River and permanently diverting the waters of the White and Stuck Rivers into it. This project was of a pioneering type, and it attracted the attention of engineers from many sections of the United States. Flood conditions have been successfully eliminated within the area improved.

In 1917, when the United States entered the World War, Mr. Roberts turned aside from this flood-control work long enough to lay out and supervise the construction of the water and sewerage systems for the Army Cantonment at Camp Lewis, Washington, accommodating 55 000 troops. These utilities, consisting of 40 miles of water mains and 30 miles of sewers, were completed in the record-breaking time of 78 days, and, although completed under the pressure of war-time preparations, they have proved satisfactory and adequate through the years during which Fort Lewis has become a permanent Army Post.

Mr. Roberts built more than forty water and sewerage systems throughout the States of Washington, Oregon, and Idaho. His later services in the engineering field were usually those of Consulting Engineer. However, he was frequently called upon as an expert witness in flood damage suits, or as a trustworthy appraiser in evaluating water systems. His integrity was as unquestioned as his engineering ability.

In December, 1936, the Tacoma Engineers' Club of Tacoma, Wash., unanimously voted to bestow an Honorary Life Membership upon Mr. Roberts. He had been active in organizing the Engineers' Club, had served as its first President, and his interest in its growth and activity had been sustained through the years. He was also a member of the American Waterworks Association.

He was for many years a member of the Tacoma Chamber of Commerce and also of the Rotary Club. In 1936, he donated a large part of his engineering library to the Tacoma Engineers' Club, and that Club placed it in the library of the College of Puget Sound, at Tacoma. He was always greatly interested in the betterment of the community wherever he lived. He found time to be an active worker in the First Church of Christ, Scientist, of Tacoma, serving as First Reader for a period of three years.

William Jackson Roberts was not only an engineer, he was a gentleman, loved and esteemed by all who knew him, especially by his "1 300 boys," of whom the writer is one.

He was married to Harriet Kitchel James, of Middlebury, Vt. To them were born three children: Arthur Kitchel, Margaret, and James Donald. Following the death of his first wife, he was married to Caroline Odell Wilmore, to whom three children were born: William Jackson, Jr., Mary Jane, and Joan.

At its meeting on April 12, 1938, the Tacoma Section of the Society passed unanimously the following resolution:

"*Whereas,* William Jackson Roberts, a beloved fellow member, having achieved works of outstanding merit and having lived a conscientious and useful Christian life, has been called to his reward; and,

"*Whereas,* the engineering profession has been uplifted by his faithful services and the whole Pacific Northwest has been benefitted by his earnestness, friendliness, efficiency, and wisdom; and,

"*Whereas,* his professional associates mourn his loss and in so doing keenly realize that Mrs. Roberts and the remainder of his family have sustained a still greater loss: Now, therefore, be it

"*Resolved,* that we, members of the Tacoma Section, American Society of Civil Engineers, bow to the Divine Will with a spirit of thankfulness for the inspiration gained by long association with William Jackson Roberts; and,

"*Resolved,* that we express deep appreciation of his professional integrity, his loyalty to ideals, his earnest efforts in behalf of his profession, and his helpfulness to younger engineers by both precept and example; and,

"*Resolved,* that our heartfelt sympathy be extended to Mrs. Roberts and others members of the family."

Mr. Roberts was elected an Associate Member of the American Society of Civil Engineers on June 6, 1900, and a Member on September 3, 1907. He became a Life Member of the Society on January 1, 1931.

HARRY EDGAR SAWTELL, M. Am. Soc. C. E.[1]

DIED JANUARY 3, 1939

Harry Edgar Sawtell was born in Keene, N. H., on September 6, 1872, the son of Albert and Abby Sawtell.

His engineering experience began about 1894 with Edward A. Buss, a mill engineer of Boston, Mass. In 1900, he took a position with the Boston Steel and Iron Company as Draftsman and Structural Designer, and in 1902 he was made Chief Engineer of the company, a position which he held for three years.

In 1905 Mr. Sawtell joined the force of Dean and Main of Boston, designers of industrial plants. In 1907 the firm was dissolved, and Mr. Main reorganized on a broader basis under his own name and placed Mr. Sawtell in charge of the Structural Department. In 1926 the organization was incorporated and Mr. Sawtell became a member and director of the firm and continued so until his death.

As head of the Structural Department of Charles T. Main, and, later Chas. T. Main, Inc., Mr. Sawtell was employed either as Consultant or Designing Engineer on a large number of important structures. Among the more notable are the foundations of practically all the buildings of the Massachusetts Institute of Technology, at Cambridge, Mass., from the first main group begun in 1913 to the Architectural Building completed in 1938.

---

[1] Memoir prepared by Charles T. Main, M. Am. Soc. C. E., and Charles W. Robinson, Esq., for joint publication by the Society and the Boston Soc. of Civ. Engrs.

Other large projects upon which Mr. Sawtell served as designers or consultant were the foundations for a group of manufacturing buildings for the Revere Sugar Refinery in Charlestown, Mass.; a group, including foundations, for the American Sugar Refining Company, in Baltimore, Md.; a group for the Lever Brothers Company in Hammond, Ind.; the principal buildings of the Gillette Safety Razor Company, the foundations of the Boston and Maine Railroad Station, and the foundations for the U. S. Parcel Post Station at the South Terminal, all in Boston. The latter involved the use of open caissons to bed-rock, extending in some cases 125 ft below the surface.

Mr. Sawtell's main interest was in foundation work, and the more difficult the problem was, the more he enjoyed it. He was a pioneer in the investigation of the physical and mechanical properties of soils and a firm believer in research, both in field and laboratory. He was widely known as an authority on foundations, and was the author of a large number of papers on engineering subjects, mainly on foundation design, which have been published in engineering journals.

In 1908 Mr. Sawtell became a member of the Boston Society of Civil Engineers. In 1926 he was made a Director; in 1929, Vice-President; and in 1931 he was elected President of that Society. His presidential address was on "Society Research" and contained valuable material on timber and soils.

For more than ten years, Mr. Sawtell was Chairman of the Boston Society's "Committee on Boston Sub-soils," and much useful material was collected, under his direction, concerning the geological formations and distribution of soils under Boston and vicinity. He devised a scheme of mapping and card tabulation, and the maps and cards were placed on file at the headquarters of the Boston Society of Civil Engineers for general use.

He was Chairman for a year and a half of a sub-committee to revise the section of the Boston Building Laws covering "Excavations and Foundations." He was Chairman also of a committee of citizens of the town of Winthrop, Mass., where he resided, to revise the Building Laws of that town.

Mr. Sawtell was a member of the Boston City Club, the Boston Yacht Club, and the Rotary Club of Boston. He was a member of the Board of Directors of the Rotary Club in 1930–1931.

Motoring and boating were his principal recreations. He was the owner of a 40-ft, 2-cabin cruiser on which, with his family, he spent considerable time every summer cruising along the coast.

He was a member of the Union Congregational Church of Winthrop, and served for many years on the Prudential Committee.

Mr. Sawtell had a keen sense of humor, was sympathetic and kindly by nature, and always had an encouraging word for his assistants and associates. His loss will be deeply felt.

On May 3, 1899, he was married to Cora Pearson, of Melrose, Mass. He is survived by his widow, one daughter, and three grandchildren.

Mr. Sawtell was elected a Member of the American Society of Civil Engineers on September 2, 1914.

WILLIAM ROBERT SCANLIN, M. Am. Soc. C. E.[1]

DIED MARCH 30, 1938

William Robert Scanlin was born in Philadelphia, Pa., on September 26, 1885, the son of Charles P. and Louisa M. Scanlin. He was educated in the Public Schools and was graduated from the Northeast Manual Training School in June, 1902. He later attended classes in engineering subjects at Drexel Institute of Technology in Philadelphia.

In 1903 he entered the employ of the Philadelphia Rapid Transit Company, where for five years he was a Junior Engineer and Draftsman in connection with the planning and construction of the Market Street Subway and Elevated Passenger Railway.

Later he was employed for six months by the New York Shipbuilding Company of Camden, N. J., as a Structural Draftsman. He left this company to take a position in the Chief Engineer's office of the Philadelphia and Reading Railway Company as Assistant Computer and Designer on an important project of grade-crossing removal in Philadelphia. He was with the company from June, 1909, to June, 1912.

At that time Mr. Scanlin entered the employ of the Philadelphia Rapid Transit Company as Structural Designer, engaged in work on buildings and the Subway and Elevated Railway System.

In 1915 he was engaged as the Engineer in charge of the design and construction of a large warehouse for the W. J. McCahan Sugar Refining Company of Philadelphia.

In 1916 he entered the employ of the City of Philadelphia as an Assistant Engineer (Squad Leader) in the Department of City Transit. He was engaged for two years on the design of sections of the projected Broad Street Subway System.

In April, 1918, he returned again to the employ of the Philadelphia Rapid Transit Company, as Structural Engineer in the Department of Rolling Stock and Buildings. In December, 1922, he was advanced to the position of Assistant to the Chief Engineer; later he was made Assistant to the Vice-President in charge of engineering, and in July, 1927, he was made Chief Engineer of the Company. He continued in this position until his death.

Mr. Scanlin's career in the engineering profession was marked by untiring attention to the details of his work, careful study of the problems before him, loyalty to his employers and associates, and a broad spirit of fairness to all who came in contact with him through business relationship.

Mr. Scanlin took an active interest in the work of the Philadelphia Section and contributed in a large measure to making the Section an influential body. He served as Director from 1926 to 1928, as Vice-President from 1929 to 1930, and as President from 1930 to 1931.

Mr. Scanlin was a member of the Engineers Club of Philadelphia, the American Society for Testing Materials, and the American Transit Association. He was also a member of the Thomas R. Patton Lodge, Free and Accepted Masons, a Past Master of Union Assembly No. 30, Artisans Order of Mutual Protection, and a member of Diligent Council No. 4, Fraternal Patriotic Americans. He was an active member of the Lutheran Church.

---

[1] Memoir prepared by Charles H. Stevens, M. Am. Soc. C. E., aided by J. H. M. Andrews and Lemuel F. Parlette, Members, Am. Soc. C. E., and William F. Scanlin, Esq.

He was married on June 27, 1906, to Ella R. Fox of Philadelphia, who, with a son, William F. Scanlin, survives him.

Mr. Scanlin was elected an Associate Member of the American Society of Civil Engineers on April 19, 1920, and a Member on October 14, 1930.

ERNEST GEORGE SCHURIG, M. Am. Soc. C. E.[1]

Died February 12, 1939

Ernest George Schurig was born in New Haven, Conn., on February 18, 1874. He attended Yale University in New Haven, and was graduated in 1894 with the degree of Bachelor of Philosophy in Engineering.

Soon after graduation he was employed by the Union Bridge Company of Athens, Pa., where he remained until 1900. In 1898 he was engaged in the erection of wharves, coaling stations, etc., for the Bridge Company at Key West, Fla., and on the Florida Keys.

At the outbreak of the yellow fever in 1900 he came north and was employed in the Bridge Engineering Department of the Illinois Central Railroad Company. From 1902 to 1904 he was with the Navy Department in the Bureau of Yards and Docks at the Philadelphia Yard, and also at New London, Conn. He prepared plans and designed structural work and checked other work for many projects, including sewer systems, coal pockets, retaining walls, and other items of architectural engineering. In 1904 he was appointed a Superintendent of Construction in the office of the Supervising Architect, U. S. Treasury Department, and was assigned to supervise the construction of the U. S. Post Office Building at Logansport, Ind. In 1906 he was transferred to the Washington office as Structural Engineer, remaining there until December, 1907, at which time he was reappointed a Superintendent of Construction for the remodeling and extension of the U. S. Post Office at Peoria, Ill. From there he was assigned to various public buildings at Rock Island, Ill.; Lincoln, Nebr.; Marshall, Mo.; and Lebanon, Pa.

In 1917 Mr. Schurig was appointed a Supervising Superintendent of Construction, with headquarters at New Haven, and he continued in that position and location until 1933, when the office was reorganized and he was assigned to Boston (Mass.), as a District Engineer, succeeding Mr. E. H. Pearson, Supervising Engineer, who was retired about that time.

In September, 1938, he retired because of disability. Until his death, his friends and family had hoped for his ultimate recovery from what started, about a year previously, as a nervous breakdown.

---

[1] Memoir prepared by Levi R. Whitted, Assoc. M. Am. Soc. C. E.

Mr. Schurig was a man of unusual ability and was highly respected by all with whom he came in contact. He was given many difficult assignments during his long service in the Treasury Department, and he completed them most successfully, and to the satisfaction of his superiors.

Mr. Schurig died of pneumonia on February 12, 1939, in New Haven. His rather sudden, although not unexpected, death is a serious loss to the Treasury Department; and his genial, generous, and cordial nature will be missed by his numerous friends.

Mr. Schurig was elected a Member of the American Society of Civil Engineers on September 12, 1916.

FRANK FORREST SINKS, M. Am. Soc. C. E.[1]

DIED APRIL 14, 1938

Frank Forrest Sinks, the son of Davis W. Sinks and Margaret (Pearson) Sinks, was born on May 12, 1873, at West Milton, Ohio. His ancestors, Prussian and English, arrived in America in 1750.

His early education was obtained in the grade and High Schools of West Milton and immediately thereafter he began his engineering career as Chainman and Rodman on irrigation surveys in Southern California.

In September, 1892, Mr. Sinks entered Rose Polytechnic Institute, at Terre Haute, Ind., from which he was graduated in 1896, with the degree of Bachelor of Science in Civil Engineering. He was a Charter Member at the Institute of the Alpha Tau Omega Fraternity.

After his graduation, he was employed as Rodman by the Chicago, Hammond and Western Railway Company and was advanced to Resident Engineer. In 1898 he became Office Engineer of the Chicago Junction Railway Company, and from 1899 to 1903 he was with the Pittsburgh Testing Laboratory as Inspector in mills, foundries, and fabricating shops, under the Resident Engineer, T. L. Condron, M. Am. Soc. C. E.

In 1903, after Mr. Condron began his private engineering practice, Mr. Sinks entered his employ as an Engineering Assistant. His work included inspections, computations of stresses, and reports on existing railway and highway bridges, as well as the designing and supervision of the erection of new structures. Later, the Condron and Sinks organization was formed, and included among its clients the Chicago and Eastern Illinois Railroad Company, the Mobile and Ohio Railroad Company, the Missouri, Kansas, and Texas Railway System, and numerous private individuals and corporations.

During the years from 1903 to 1906, when reinforced concrete was in its infancy, the firm of Condron and Sinks contributed constructive work in the design and development of reinforced concrete structures, and Mr. Sinks was regarded as one of the leaders in the field. He originated and patented a type of flat-slab floor design which, later, became known as the "Akme System." The special characteristic of this type of design was the placing of all reinforcing bars in but two directions, instead of four directions, in such a manner as to make the design "structurally determinate"; also, in this two-way system, the percentage and distribution of reinforcement for different spans and loads could be proportioned in accordance with generally accepted rules or formulas for designing girders and slabs. The Akme system was extensively used in the construction of many buildings erected in at least thirty-five cities of the United States, and in Canada.

---

[1] Memoir prepared by John Arrington, Esq., Seattle, Wash., and T. L. Condron, M. Am. Soc. C. E.

In August, 1908, Mr. Sinks was temporarily engaged by the Corrugated Bar Company, of St. Louis, Mo., to go to the Pacific Coast, and assist its agents there in the promotion and sale of its products.

The firm of Condron and Sinks continued until 1911, when Mr. Sinks withdrew and returned to Seattle, Wash., and the Pacific Coast where he had been very successful in promoting the corrugated bar and had made many friends. During the summer of 1911 he induced the Pacific Coast Steel Company (later, a Pacific Coast subsidiary of the Bethlehem Steel Company) to roll corrugated bars from old railroad rails for reinforcing concrete. This character of steel bar was at first not favored by engineers of the Pacific Northwest for use in reinforced concrete structures, but Mr. Sinks, together with the organization which he had formed, succeeded in establishing re-rolled corrugated bars as an acceptable type of reinforcing material in the Pacific Northwest.

In January, 1914, he was engaged by the Pacific Coast Steel Company, as Sales Engineer in charge of reinforcing steel sales, and, later, was made Sales Manager in charge of domestic and foreign sales of the Seattle plant.

In 1918, after America had entered the World War, Mr. Sinks resigned as Sales Manager of the Pacific Coast Steel Company, to accept the position of General Manager of D. W. Hartzell, Incorporated. This Corporation had leased some poorly arranged existing shipyards at Winslow, Wash., and had secured contracts from the United States Shipping Corporation for installing machinery and equipment in ten wooden hulls that had been launched to help win the war. This Corporation was also engaged in dry docking and marine repair work. Again, his natural ability asserted itself as General Manager. He re-arranged and remodeled these yards, installed new equipment, and perfected an organization for their operation which was as complete as any in the Pacific Northwest.

In 1921, he returned to the private practice of engineering and established himself, in Seattle, as a Consulting and Contracting Structural Engineer. He was retained to go to New York, N. Y., to revise the structural plans of the Hotel Olympic, a 1 000-room hotel to be constructed in Seattle. The plans had been prepared by New York architects and engineers for the use of structural steel, but the building was built of reinforced concrete in accordance with Mr. Sinks' recommendations.

In 1930, he designed and supervised the construction of the Reinforcing Bar Fabricating Plant and Stock Shed, in Seattle, for the Pioneer Sand and Gravel Company, and became Engineer and Manager of that Department. He remained with that Company and in that capacity until 1935, when he returned to the private practice of engineering.

Mr. Sinks was married on February 25, 1911, to Laura Castle Nichols, of Chicago, Ill., who survives him. They had no children.

He was possessed of a winning genial personality and made friends wherever he went. He was very sincere, quiet, and unassuming, and was not only admired for his technical ability but for his fine character, his always sound common sense, and his keen kindly humor. He not only made friends with all with whom he came in contact, but he retained his many friends throughout his life, even from his college days and early associations, when associations were intimate, free from the competition of commercial life, when likes and dislikes were frank and unfettered.

The following quotation is taken from a letter received by Mrs. Sinks from A. M. Young, M. Am. Soc. C. E., at the time of her husband's death. This letter is quoted as it is typical of the many letters which she received and shows the esteem in which her husband was held:

> "I want to express to you my very great sorrow at the passing of your husband. I had known him for a very great many years. I met him as early as 1914. I had known him by reputation for many years before that. At the Cement Show at the Coliseum at Chicago, about 1906, I remember the models of his patents. I used these patents and paid him royalties. I never thought that I would come to know him as well as I did, for in engineering he stood on a pedestal which few of us will ever reach. It has been one of the high lights of my experience to know and enjoy the friendship of Frank.
>
> "Frank's assistance on our work was of the greatest value to us. He was absolutely dependable and he got things done. We will miss him very greatly.
>
> "Frank's contribution to the art of building is so outstanding as to need no comment. No concrete engineer has made a larger. It is not often that a man lives to see his conceptions generally adopted and acclaimed, and it must have been a very great satisfaction to him to have participated so largely and effectively in improved building methods."

Mr. Sinks was interested in mining and loved Nature and the great outdoors, especially the mountains. His engineering took him into all parts of the United States, but his vacations were spent with his wife, accompanied by a guide, pack and saddle horses, and hunting dogs, traveling through the Cascade Mountains, the Olympic Mountains, and the mountains of British Columbia, hunting and fishing, and studying bird and plant life.

Mr. Sinks was elected an Associate Member of the American Society of Civil Engineers on May 2, 1906, and a Member on June 4, 1907. He was also a member of the Western Society of Engineers.

WILSON FITCH SMITH, M. Am. Soc. C. E.[1]

DIED NOVEMBER 29, 1937

Wilson Fitch Smith, the son of Fitch W. Smith and Isabel C. (Eagle) Smith, was born in New York, N. Y., on August 2, 1871.

---

[1] Memoir prepared by George Perrine, M. Am. Soc. C. E.

"Wilson Fitch," as his close friends referred to him, attended Berkeley School in New York City, where he prepared for entrance into the School of Mines at Columbia University, when that institution was situated at Forty-Ninth Street and Madison Avenue. While attending the School of Mines, he excelled in his studies and was also proficient in athletics; he took part in inter-class and inter-collegiate games—his favorite events being sprints and hurdling. His fraternity was Alpha Delta Phi. The degree of Civil Engineer was conferred upon him in June, 1894.

Immediately after graduation Mr. Smith was appointed Assistant Instructor in Surveying at the Summer School conducted by Columbia University at Bantam, Litchfield County, Conn., on a farm owned by the University. Engineering students attended this school for three summers from June to September. This summer course afforded these students more practical instruction than a corresponding course at any other engineering school.

In October, 1894, Mr. Smith joined the Engineering Staff of the New York Central Railroad Company as Volunteer Assistant, which means, that one in that position worked without stipend until he proved his worth. The first position held by him from October, 1894, to April, 1895, was Rodman.

From April, 1895, until October, 1896, he was Assistant Engineer in charge of a Field Party. It is quite likely that the meager pay given to beginners in the railroad field is discouraging to many of the more ambitious. If Mr. Smith had continued with the Railroad Company, he would, without a doubt, have developed into a valuable member of the Executive Staff.

After severing his connection with the New York Central Railroad Company, Mr. Smith entered the employ of R. W. Hildreth and Company, as Shop Inspector. The more important structures upon which he was engaged were the inspection of the structural steel for the Commercial Cable Building and the Queens Insurance Buildings, in New York City.

While in Berkeley School, Wilson Smith attended military drills. In later years, and about this time, he joined Squadron A, N. Y. N. G.

From January, 1897, to June, 1898, he was in the employ of the late William Barclay Parsons, Hon. M. Am. Soc. C. E., Chief Engineer of the Rapid Transit Commission of New York City. His first duty in this position was to prepare a perspective design for a viaduct to carry a proposed extension of the Amsterdam Avenue Line of the Third Avenue Railway Company from the high ground at 190th Street, north to Kingsbridge. The structure was very attractive in design, but, unfortunately, the Railway Company did not construct the viaduct. Upon the completion of this design, Mr. Smith was put in charge of a certain portion of contract drawings for the Rapid Transit Underground Railway. The original detail and alignment, in existence when Mr. Parsons was promoted from Assistant Engineer to Chief Engineer of the Rapid Transit Commission, was very typical and sketchy, because of a scarcity of funds.

At that time, and for a little while afterward, the Rapid Transit Subway was considered a great venture, and capitalists were hard to convince of its possibilities and great value as an investment. Mr. Parsons and Mr. John B.

McDonald, the most prominent contractor at that time, convinced Mr. August Belmont, banker, that the subway was feasible and could be built at reasonable costs, and from that time rapid transit was destined to become a fact.

The typical plans mentioned previously were immediately elaborated upon, and from them the first contract drawings for the first subway were developed. Mr. Smith had charge of preparing a certain portion of these plans.

In 1898, progress in the preparation for the receiving of bids for the construction of the subway was delayed. Mr. Parsons was engaged by certain financial interests to go to China with a party of engineers to make a survey for a railroad from Canton to Hankow.

During the lull in subway progress, Mr. Smith accepted a position with the late F. Stuart Williamson, M. Am. Soc. C. E., Consulting Engineer, whom he met through his association with Mr. Parsons. His duties in this position were in connection with the design and preparation of plans for the Riverside Drive Viaduct at 129th Street, New York City. The period covered by this engagement was from June, to August, 1898, inclusive. From August to November, 1898, he was in the service of the Laflin Rand Powder Company, at Pompton, N. J., making a complete topographical survey of its properties.

From November, 1898, until June, 1900, Mr. Smith was in the employ of the late George Shattuck Morison, Past-President and Hon. M. Am. Soc. C. E., Consulting Engineer. While in this engagement, he obtained valuable experience in the design of bridges of the most elaborate types and magnitude. Two of the bridges for which he assisted in preparing plans were the Atchison Bridge, Competitive Design for Memorial Bridge across the Potomac River at Washington, D. C., which comprised five 180-ft span masonry arches; and the new superstructure for the Columbus Bridge, for the Mobile and Ohio Railroad Company.

Mr. Smith returned to subway work in June, 1900, as Assistant Engineer of the Rapid Transit Commission. Because of his former connection with the staff of the Chief Engineer, the Civil Service Commission approved his application without formal examination, upon the request of the Chief Engineer. This fact is probably recorded in the Minutes of the Board of Transportation. Mr. Smith was assigned as Section Engineer of that part of the Broadway route from West 103d Street to West 125th Street. His assignment on this section terminated in June, 1903, when he was put in charge of the reinforced concrete tunnel under Lenox Avenue from 145th Street to 148th Street, and also the tunnel under the Harlem River. The reinforced concrete subway was called the "bird cage" type. This type of construction was discontinued after a short period. The river tunnel was of a novel and original design, devised by the contractors for whom the late William H. Burr, M. Am. Soc. C. E., was Consulting Engineer.

After this work was completed, Mr. Smith was appointed Division Engineer of the Kensico Division, Board of Water Supply of New York City. This appointment was gained through the recommendation to the Chief Engineer, the late J. Waldo Smith, Hon. M. Am. Soc. C. E., by his close friend and former comrade in arms in Squadron A, the late Merritt H. Smith, M. Am. Soc. C. E., Deputy Chief Engineer of the Board.

The Division Engineer's Staff made all the surveys, both topographical and lines and grades for the construction of the dam and appurtenant structures. There was included in this Division, 4 300 ft of aqueduct in tunnel, gate chambers, aerating basin, and other structures. This assignment covered a period of eleven years from May, 1906, to October, 1917.

The Kensico Dam was of cyclopean masonry, with a rough rock face, the total content being 900 000 cu yd. The length of the dam is 1 850 ft, with a total height at center of 307 ft. The top is 28 ft wide under the coping.

After the completion of this term of service, and from October, 1917, to May, 1918, Mr. Smith was Resident Engineer of the Division of Shipyard Plant, of the Emergency Fleet Corporation, stationed with the Merchants Shipbuilding Corporation, at Bristol, Pa. This engagement covered the supervision and construction of shipyard and housing at this plant. The cost of this work was about $15 000 000, and all expenditures were under the control and approval of Mr. Smith.

This connection with the Merchants Shipbuilding Corporation continued until September, 1918, when Mr. Smith was Manager in charge of a housing development of the industrial Town of Harriman, Penna. Later, he was Special Assistant to the President and Vice-President of the Corporation, engaged in investigation and reports. During 1921 and 1922, Mr. Smith was Manager in charge of properties at Harriman Yard.

After this, he was Chief Engineer of the Bear Mountain Hudson River Bridge Company, in charge of the construction of the Bear Mountain Bridge, crossing the Hudson River north of Peekskill, N. Y.

From November, 1925, to the date of his death, Mr. Smith was Vice-President and Director of the Dutchess Bleachery, Incorporated, and the Rockland Finishing Company, Incorporated, at Poughkeepsie, N. Y. He was a member of the University Club of New York City and the Quill and Arkwright Clubs, also of New York City.

Mr. Smith is survived by his mother, Mrs. Fitch W. Smith, a sister, and three children, one of whom is Dr. Wilson Fitch Smith, Jr. Mrs. Wilson Fitch Smith, who died about two years before her husband, was Alice Mary Stimson, daughter of the Rev. Henry Albert Stimson and niece of the Hon. Henry L. Stimson, former Secretary of State.

Wilson Fitch Smith was one who had a charming personality. Some thought him one with whom it was difficult to become acquainted. To those who knew him well, however, he was a man with a keen sense of humor, very pleasant company, and a faithful friend. In business, he was very painstaking, accurate, and conscientious. His assistants respected him on account of his thorough technical knowledge and skill as a Construction Engineer, for his fairness toward them, and for his appreciation of their faithful services.

Mr. Smith was elected a Junior of the American Society of Civil Engineers on January 3, 1895; an Associate Member on May 1, 1901; and a Member on February 6, 1912.

GEORGE PUTNAM STOWITTS, M. Am. Soc. C. E.[1]

DIED MARCH 5, 1938

George Putnam Stowitts was born on March 19, 1879, in Westfield, N. Y., the son of Cornelius S. and Maria (Putnam) Stowitts. He attended Hamilton College, at Clinton, N. Y., during the years 1896 and 1897, and Rensselaer Polytechnic Institute, at Troy, N. Y., from 1898 to 1900.

Upon leaving Rensselaer he entered the Engineering Department of the New York Central Railroad Company, where he remained until 1920, occupying, successively, the positions of Chainman, Rodman, Draftsman, Assistant Engineer, Chief Draftsman, and Assistant Designing Engineer, on the Lines East of Buffalo. In 1910 he became Designing Engineer and in the next eight years prepared plans, specifications, and estimates for a great variety of work, including the Castleton Cut-Off across the Hudson River south of Albany, N. Y.; the Gardenville Yard at Buffalo, N. Y.; piers at Weehawken, N. J.; extensive four-tracking and double-tracking; and new engine-houses. During this period he revised many old standards and established new ones in many important fields.

In 1918 he was appointed District Engineer of the Eastern District of the New York Central Railroad Company (embracing the Hudson, Harlem, Putnam, River, and Pennsylvania Divisions) and had charge of the contract construction work, including notably some important grade revisions, four-tracking, station buildings, and terminals.

In 1920 Mr. Stowitts resigned from the New York Central Railroad Company to take charge of the construction of a ship repair plant at West New York, N. J., as Chief Engineer of the Lord Dry Dock Company.

From 1922 to 1925 he engaged in consulting practice at New York, N. Y. He was associated with the late George F. Swain, Past-President and Hon. M. Am. Soc. C. E., of Boston, Mass., in a report and project for passenger terminals at Toronto, Ont., Canada. He was retained by the City of New York to report on valuation of surface, elevated, and subway lines. He was associated with the late Francis Lee Stuart, Past-President, Am. Soc. C. E., under a committee of railroad presidents to make a complete study and plan for improving the railroad problem in the Metropolitan District in connection with the City of New York and harbor affairs. He did consulting work for the Foundation Company of New York on its important railroad problems.

In 1925 Mr. Stowitts became Engineer of Construction of the Seaboard Air Line Railway and the Seaboard All-Florida Railway Companies, having charge of the location and construction of their new line from West Palm Beach to Miami, Fla. This was a 75-mile extension with a 25-mile branch. It included 35 bridges (7 of which were movable) and 20 passenger stations.

When the Cincinnati Union Terminal Company was organized in 1927 to build a single terminal to replace the scattered passenger stations of the numerous railroads entering Cincinnati, Ohio, Mr. Stowitts was made Engineer of Design; and in 1929 when construction began, he accepted the position of Engineer of Construction, to bring all the railroads to one terminal. He worked out studies and estimates, developed the adopted scheme, and had charge of the design and construction of the whole enterprise, involving 6 500 000 yd of grading, 25 000 tons of steel, 30 000 yd of concrete, 15 000 piles, and a total cost of about $41 000 000. The success of his solution of the many difficult problems involved, such as topography, foundations, and operation, is attested by its performance during subsequent floods.

---

[1] Memoir prepared by E. F. Kriegsman and H. M. Waite, Members, Am. Soc. C. E.

Upon the completion of the Cincinnati Terminal in 1933, Mr. Stowitts engaged in consulting practice in Cincinnati. Later in that year he was appointed State Engineer Inspector for Iowa, of the Federal Public Works Administration. In 1935 he was made Chief Engineer of the Inspection Division. When the PWA was re-organized on a regional plan basis in November, 1937, Mr. Stowitts became Engineer of the New York Region.

His success in engineering work was due to his organizing ability in training personnel and securing their loyal co-operation. His ability to study out the solution to a difficult railroad problem was outstanding.

Mr. Stowitts was a member of the Sigma Phi fraternity, the Society of Terminal Engineers, and the Georgetown Presbyterian Church of Washington, D. C.

Mr. Stowitts greatly loved out-door occupations. He was an expert in gardening, kept bees, and his sport was upland hunting of quail and partridge. The making of stocks for shotguns was a hobby which gave him great pleasure. His taste in reading was catholic, with especial emphasis on the value and beauty of Greek literature. He was of the opinion that a man widely read, with a broad, general as well as technical education, and a vital interest in nature, made the best sort of engineer.

He was married to Edith Aylworth Gillespie on October 3, 1906, at Albany, N. Y. Three daughters, Emily, Mary Gardner, and Rhoda Putnam, were born to them. Mrs. Stowitts and one daughter, Mrs. Gaylord Marsh Merriman (Emily), and two sisters, Mrs. G. A. Hulbert and Mrs. H. Frank Paddock, survive.

On March 5, 1938, Mr. Stowitts died suddenly of a heart attack, at the terminal of the Lackawanna Railroad, in Montclair, N. J., where he had lived since the previous December. Interment was at Kensico Cemetery.

Mr. Stowitts was elected an Associate Member of the American Society of Civil Engineers on June 3, 1908, and a Member on September 3, 1912.

EMORY SUDLER, M. Am. Soc. C. E.[1]

DIED APRIL 21, 1938

Emory Sudler was born in Anne Arundel County, Maryland, on February 14, 1870, the son of Colonel and Mrs. John (Emory) Sudler. He attended the public schools and the Baltimore (Md.) City College, from which he was graduated in 1888.

---

[1] Memoir prepared by Guy Bonney, M. Am. Soc. C. E.

After his graduation he obtained his first engineering position as Draftsman and Instrumentman on town-site development at Buena Vista, Va., where he remained for about three years.

In 1891, Mr. Sudler returned to Baltimore, and with the exception of a period of two years—during which time he was employed by the Baltimore and Ohio Railroad Company on location in West Virginia, and by the Louisville and Nashville Railroad Company in Kentucky—he remained continuously in that city until 1914. He served for three years as Transitman and Assistant Engineer on river and harbor surveys relative to improvements for Baltimore's water shipping; one year as Draftsman for the Electrical Subway Commission of Baltimore; and for fifteen years he was with the Baltimore City Water Department.

At the time that he entered the service of the Water Department many improvements were necessary, due to the rapid growth of the city, and because of the outstanding ability displayed by Mr. Sudler, the development of a large part of these improvements, from preliminary to finished stages, was given over to his direction. The most outstanding of these improvements were the Roland Park stand-pipe, preliminary surveys and studies for a 20 000 000 000-gal impounding reservoir on the Gunpowder River, and investigations of storage reservoir sites, culminating in the design and construction of Lake Ashburton, a 210 000 000-gal reservoir.

In 1910, when the Gunpowder River improvements for the water supply of Baltimore were made possible by appropriations obtained for that work, Mr. Sudler was made Division Engineer in charge, and under his direction these improvements were designed, and to a large extent completed by the time of his resignation in 1914. In addition to the impounding dam, gatehouse, and conduit connecting to an existing feeder tunnel, several miles of highways and two long highway bridges replacing flooded roads were constructed. At the same time he also designed and constructed distributing mains of steel and concrete within the city limits, which, too, were a part of this construction program. In 1914, he resigned from the Water Department and spent a year or more of leisure in his native county, in Maryland.

From 1916 until 1919, Mr. Sudler was with the United States Government as Engineer on design and construction of wharves, docks, bulkheads, and in charge of dredging operations at the Norfolk, Va., Army Supply Base and Terminal.

He was employed from 1919 until 1929, by the Ambursen Construction Company as Chief Engineer and played an active part in the large number of dams and power-houses designed and constructed during this period by that Company.

From 1930 until his death, Mr. Sudler was more or less inactive in engineering work. He was employed for a short time on the preparation of data to be used in the legal battle between New Jersey and New York, N. Y., concerning the diversion of water from the Delaware River; and spent some time with the Westchester County Park Commission and the Department of Parks, in New York City.

Although throughout his career there is exhibited a high degree of talent and thoroughness, his outstanding work, and that which appealed to Mr. Sudler most, was the design of dams and other hydraulic structures. While with the Baltimore City Water Department he directed the design of the Loch Raven Dam and the earth dam at Ashburton Reservoir. During the ten years he was with the Ambursen Company, he designed and supervised the installation of automatic crest gates for the Patillas Dam, in Puerto Rico; created the design in an engineering competition, which was selected by a Committee of Engineers, covering the reconstruction of the Oklahoma City, Okla., Water-Works Reservoir; and made the preliminary design for the Rodriguez Dam, in Mexico. This dam, completed in 1938, is 250 ft in height and is the highest dam of the Ambursen type in the world. Besides designing many other dams that were built by this Company during this period, he patented the Sudler Radial Gate, an under-sluice of the Tainter gate type, suitable for large openings under head.

Mr. Sudler was highly educated, and this education, obtained through the years by hours of study and reading, extended far beyond the field of engineering. A gentleman, an engineer, and a Christian in the true sense of the words—his record bears out this statement.

He was unmarried, and is survived by his mother, Mrs. John Emory Sudler, a brother, Ralph Eric Sudler, and a sister, Elsa deTalma Sudler.

Mr. Sudler was elected an Associate Member of the American Society of Civil Engineers, on September 5, 1911, and a Member on October 12, 1925.

ALFRED FRANCIS THÉARD, M. Am. Soc. C. E.[1]

DIED JANUARY 2, 1939

Alfred Francis Théard was born in New Orleans, La., January 29, 1865. His ancestors, on both sides, were members of old and distinguished Louisiana families. His father, Judge Paul E. Théard, and his mother, Athenais (Pilie) Théard, were representative of that ante-bellum culture and refinement for which the old South was noted.

Mr. Théard's early education was obtained at the Jesuit College in New Orleans, supplemented by more extended studies at Spring Hill College at Spring Hill, Ala., from which institution he was graduated in 1881. His first activities were in commercial pursuits, but his aptitude for scientific study led him to seek a connection in the Engineering Department of the City of New Orleans, in 1893. He remained there until 1896, when he became identified with the office of the New Orleans Drainage Commission—first, as Draftsman, and later, as Assistant Engineer. In 1903 the New Orleans

---

[1] Memoir prepared by a Committee of the Louisiana Section composed of John Klorer, J. H. O'Neil, and G. G. Earle, Members, Am. Soc. C. E., assisted by M. T. Ducros, Esq.

Drainage Commission was consolidated with the Sewerage and Water Board of New Orleans. In the transfer of forces, Mr. Théard was retained and later, in 1913, became Principal Assistant Engineer in Charge of Drainage. He held this post until January 1, 1934, when he was elevated to the position of General Superintendent of the Sewerage and Water Board of New Orleans.

His was the unusual privilege of participating actively, step by step, in the development of the unique system of artificial drainage in New Orleans from the time that the total capacity of the City's drainage pumping stations was rated at approximately 1 000 cu ft per sec, to the present high degree of efficiency represented by ten drainage pumping stations with an aggregate capacity of 25 000 cu ft per sec.

In addition to his engineering qualifications, Mr. Théard possessed talents as an architect which were recognized in the engagement of his services in that capacity by the U. S. Engineer Department to prepare plans for the completion of the Chalmette Monument in New Orleans on the site of the memorable and decisive victory of General Andrew Jackson over the British Forces on January 8, 1815. Subsequently, in 1919, he was engaged by the Louisiana-Vicksburg Park Memorial Commission to prepare plans for the design and erection of the Louisiana Memorial Monument in the National Military Park at Vicksburg, Miss.

He was one of the organizers and charter members of the Louisiana Engineering Society and served as President of the organization during 1902. He was also a member of the Governing Board of the Southwest Section of the American Water Works Association in 1938.

In 1908 Mr. Théard engaged in the successful effort to have the State Legislature pass a law regulating the practice of Civil Engineering and Surveying in Louisiana, the first State in the Union to have such a law.

In 1937 he was the recipient of the Veterans' Plaque from the American Public Works Association—"Awarded for long and faithful services, to Mr. Alfred F. Théard, who has served New Orleans continuously since 1893."

Of commanding presence and bearing, and apparently the picture of health, in spite of advancing years, his unexpected death came as a surprise and shock to his friends and associates. He had been at his desk, actively engaged in his official duties to within a few weeks of his death, dispensing those with a geniality and agreeableness for which he was noted, when a sudden heart attack, upon leaving the office after the day's toil was over, made him request to be taken home. He rallied sufficiently to return to his office for about a week, when a second similar attack ended fatally.

His long and useful career with the Sewerage and Water Board of New Orleans is testified to in the following tribute paid him by that Board:

> "In the death of Alfred Francis Théard the Sewerage and Water Board has suffered a loss of an outstanding official and citizen, whose value and worth cannot be measured in words.
>
> "In the various relations of life, and especially in the great cause of the Sewerage and Water Board, and Civic Affairs, he brought to the performance of every duty, whether allotted to him, or voluntarily as-

sumed, an earnestness of purpose which never wavered, and, at all times, the measure of his strength was the limit of his willingness.

"He was a true and sincere man in his intercourse with his fellowman. He knew of one rule of conduct and his even and uniform application was never affected by any influence of station or condition or mutation of fortune and was also marked and distinguished by that species of kindly courtesy, which seems born of a desire to serve.

"As we pay to his endearing memory this tribute of our love, our heartfelt sympathy goes out to those across whose path has fallen the heavy shadow of this great grief, and we pray that it may please a merciful Providence to lift up the light of His Countenance upon them and send to them that peace and comfort and consolation which passeth all understanding and which no human agency, however loving and sympathetic, can give."

He was married on October 17, 1887, to Marie Delvaille, of New Orleans, who, with two sons, Delvaille and Albert Théard, and a daughter, Mrs. Marie Théard Moses, survives him. He also left, as immediate members of his family, an elder brother and two sisters.

Mr. Théard was elected a Member of the American Society of Civil Engineers on March 2, 1915.

THOMAS HENRY TUTWILER, M. Am. Soc. C. E.[1]

Died September 3, 1938

Thomas Henry Tutwiler was born on September 22, 1866, in Palmyra, Va., the son of Thomas Henry and Caroline (Sloan) Tutwiler. He received his early education in the public schools and High School of Palmyra, and was tutored privately in Engineering.

He began his engineering career in 1882 when he was employed as Rodman by the Richmond and Alleghany Railroad Company, the Georgia Pacific Railroad Company, and several smaller companies, until 1886. The next two years he was with the Georgia Pacific Railroad Company (later, the Southern Railway Company) acting first as Assistant Resident Engineer on ten miles of construction in mountainous country; then as Transitman with a party that made more than 100 miles of finished railway location (much of the time in complete charge of the party); and then as Resident Engineer in charge of 10 miles of construction, including the Sunflower River Draw-Bridge.

In 1889, Mr. Tutwiler was employed by the Louisville, New Orleans and Texas Railroad Company (later, the Yazoo and Mississippi Valley Railroad Company) as Assistant Engineer in charge of 25 miles of location and construction, reporting to the Division Engineer. Following this engagement he served as Division Engineer in charge of 40 miles of construction, including track-laying, ballasting, depot buildings, and 150 miles of location.

---

[1] Memoir prepared by James H. Haylow and W. F. Schulz, Members, Am. Soc. C. E., and Harry N. Howe, Assoc. M. Am. Soc. C. E.

In 1892, he became Assistant Engineer on the Yazoo and Mississippi Delta Levee Board, in charge of levee construction.

From 1893 to 1900, Mr. Tutwiler was with the New Orleans (La.) Traction Company, starting as First Assistant Engineer in charge of track construction, design of special track work, bridges, and other structures, and then as Chief Engineer in charge of construction and maintenance, both track and overhead, directing all designs.

In 1901, he was Superintendent of street railway construction at Birmingham, Ala., for Ford, Bacon and Davis, Engineers, of New York, N. Y. The following year he was Engineer at Kansas City, Mo., including work on the cable system for the same firm; and, in 1902, he was in charge of rehabilitating the Nashville Street Railway, at Nashville, Tenn.

Mr. Tutwiler was elected Vice-President and General Manager, and then President, of the Memphis (Tenn.) Street Railway Company, in 1905, during which time the entire system was reconstructed and brought to a high state of efficiency, which was continued throughout his tenure of office.

In 1923, he was elected President and Director of the Memphis (Tenn.) Power and Light Company. This system was in a run-down condition but he completely rebuilt it so as to provide sufficient capacity and good dependable service. One of his most outstanding achievements was the perfecting of the entire organization, every person of which held him in the highest respect and gave him full co-operation. He retired in 1930. The following tribute is quoted from the *Memphis Commercial Appeal,* of September 4, 1938: "His interest in community growth and welfare has been keen, intense, and sustained. No citizen stands higher in the community."

When the project of moving Southwestern University from Clarksville, Tenn., to Memphis took form, Mr. Tutwiler was one of its originators. In the initial campaign to raise the $500 000 needed to engineer the move, he was a tireless worker and executive, as he was in subsequent drives for funds for the institution. After his retirement from business, the affairs of Southwestern were his principal interest. Dr. Charles E. Diehl, President of Southwestern University, writes of him:

> "The day was never too long nor the night too dark for him to do something that might benefit Southwestern. Efforts in its behalf were the one thing he never ceased to attempt, even during his last illness. Whenever the need came, he was eager to drop everything else and devote himself to the school's interest."

Mr. Tutwiler was a member of the Tennessee Club, the Memphis Country Club, the Louisiana Engineering Society, and The Engineers Club of Memphis.

He was married, on December 19, 1894, to Mary E. Goodloe, who survives him. He also leaves two daughters, Mrs. Mary T. Langmead and Mrs. Zena Land, and one son, Thomas H. Tutwiler, Jr.

Mr. Tutwiler was elected a Member of the American Society of Civil Engineers on June 4, 1902.

CHARLES COURTLANDT WHITAKER, M. Am. Soc. C. E.[1]

Died August 3, 1938

Charles Courtlandt Whitaker was born in Brooklyn, N. Y., on August 19, 1877, the son of Charles Courtlandt Whitaker and Etta (Myers) Whitaker. He received his general and technical education in Brooklyn, and started in the engineering profession, holding increasingly important positions with such firms as Thompson-Starrett Company, Levering and Garrigues Company, Post and McCord, and Frank B. Gilbreth, all in New York, N. Y. His work consisted primarily of drafting, detailing, design, and supervision of construction.

From 1909 to 1923, Mr. Whitaker was employed by the Truscon Steel Company of Youngstown, Ohio. During his first year and a half with this company, he held the position of Sales Engineer, and for the remainder of his fourteen years with the company, he was Manager of Sales for the Atlanta, Ga., office, covering the Southeastern territory. During this time he designed, or supervised the design, of many of the important reinforced concrete structures in the Southeast, including schools, hotels, court houses, bridges, factory buildings, and hospitals.

From 1923 to 1938, Mr. Whitaker operated his own business as a Consulting and Designing Engineer, preparing plans, and specifications and supervising construction from his own office in Atlanta. Among his best-known works are the following buildings: 9-story Hicks Hotel and Carnegie Library in Savannah, Ga.; Wells Theater in Augusta, Ga.; 18 bridges for Hillsboro County, Florida; 172-ft Booker Creek Bridge and Don ce Sar Hotel (500 rooms) in St. Petersburg, Fla.; Supreme Court Building in Tallahassee, Fla.; National Paper Company and Scripto Manufacturing Company plants, and buildings for Montag Brothers, Inc., in Atlanta.

He was married on March 16, 1911, to Anna May Gregory of Windsor, Ont., Canada, who survives him. They had two sons, Charles Courtlandt and John, both of whom survive Mr. Whitaker.

His principal hobby was his business, which he thoroughly enjoyed, although in his youth he was quite an enthusiast in sail-boating, and also won a number of prizes in bicycle racing in and around New York. In his later life he was very fond of golf and motoring.

During his lifetime, he served on all committees of the Georgia Section of the American Society of Civil Engineers, and also held all offices, including Secretary, Vice-President, and President. He was active in the Atlanta Athletic Club and the Atlanta Lions Club, and was a director of the Atlanta Motor Club, at which time he served on the traffic survey of Atlanta, later being elected to a membership on the National Commission of Traffic Survey. He was an honored and respected citizen of Atlanta, where he had many professional and personal friends.

Mr. Whitaker was elected a Member of the American Society of Civil Engineers on January 14, 1924.

---

[1] Memoir prepared by Robert S. Fiske, Atlanta, Ga.

FRIEND PITTS WILLIAMS, M. Am. Soc. C. E.[1]

DIED FEBRUARY 20, 1939

Friend Pitts Williams was born at Richmond Mills, N. Y., on December 18, 1875, the son of Allan Irving Williams and Emily (Barton) Williams. His early education was received at the Olean High School at Olean, N. Y. He entered Cornell University, at Ithaca, N. Y., in 1895, and was graduated from that institution in 1899 with the degree of Civil Engineer.

For four years, beginning June, 1899, Mr. Williams was employed in the Engineering Department of the Pittsburgh, Shawmut and Northern Railroad Company as Assistant and Resident Engineer on design, location, and construction. His work covered 50 miles of road in New York and Pennsylvania.

In June, 1904, he was appointed Assistant Engineer in the Department of the State Engineer and Surveyor of the State of New York. In this capacity he was engaged on highway work in Westchester County and in the designing department of the New York State Barge Canal.

Mr. Williams was promoted to Resident Engineer in June, 1906, and had charge of location surveys at Lyons, N. Y., construction of five locks and dams on the Mohawk River near Amsterdam, N. Y., and the dredging and construction of various works along the 30 miles of Hudson River near Mechanicsville, N. Y. In April, 1914, he was appointed Division Engineer, in charge of the Western Division of the department, with headquarters in Rochester, N. Y. There he had charge of the work on some 140 miles of canal, including the design and construction of the Bushnell Basin Trough at Rochester Harbor.

Mr. Williams was appointed Special Deputy State Engineer in January, 1919, with headquarters at Albany, N. Y. In this capacity he had charge of the work on the entire canal system. The principal construction during his administration was in connection with Barge Canal terminals and particularly with the grain elevator at Gowanus Bay, in New York, N. Y. On completion of the canal work, in 1921, this position was abolished.

In May, 1921, Mr. Williams was appointed Engineer-Secretary of the newly created Water Power Commission and served with that Commission and its successor, the Water Power and Control Commission of the State of New York, for the remainder of his active life. In that capacity he organized the work of the Water Power Commission and, in connection with the activities of the Commission, made extensive studies of water-power matters connected with the Niagara and St. Lawrence rivers and the effect of the Chicago Drainage Canal diversion on these rivers. He collected and presented material for important litigation undertaken during that period. Ill health compelled his retirement from the State service in November, 1938.

---

[1] Memoir prepared by R. Suter and Ernest D. Hendricks, Members, Am. Soc. C. E., and John P. Newton, Assoc. M. Am. Soc. C. E.

In 1906 Mr. Williams was married to Alma Horton. She died in 1927. Two daughters, Grace and Emily L. Williams, survive.

Mr. Williams was a member of the Albany Section of the New York State Society of Professional Engineers, which he assisted in organizing, and of the Albany Society of Civil Engineers of which he was President in 1927. He was a member and Director of the University Club of Albany; a member of Ondawa Lodge, F. and A. M., Mechanicsville; of Beta Theta Pi Fraternity; and of the First Presbyterian Church of Albany.

He possessed the attributes of a true gentleman in the strictest sense. He was a conscientious and capable engineer. Ever loyal to his superiors and considerate of his subordinates, it may be said truly that all with whom he had professional and social contacts were his friends and held him in unusually deep respect and esteem.

Mr. Williams was elected a Member of the American Society of Civil Engineers on July 1, 1909.

CHARLES BEATTY WILSON, M. Am. Soc. C. E.[1]

Died April 8, 1938

Charles Beatty Wilson was born in York County, South Carolina, on September 6, 1871. He was the son of James and Mary (Williamson) Wilson. His father, the son of Presbyterian missionaries, was born in Allahabad, India. Mr. Wilson was brought to Nashville, Tenn., when he was a very young boy and lived there until three years before his death, when he moved to Honolulu, Hawaii, where he passed away on April 8, 1938. He attended Montgomery Bell Academy, and, later, Vanderbilt University, at Nashville, where he specialized in Civil Engineering.

In 1889, he was employed by the Nashville, Chattanooga, and St. Louis Railroad Company, and was with that line for eighteen years. During this time he was engaged in maintenance and construction work—one project being a bridge over the Tennessee River, at Johnsville, Tenn.—and rose to the position of Assistant Chief Engineer.

In 1907, Mr. Wilson was made Assistant Engineer for Davidson County, Tennessee, during the construction of the Sparkman Street Bridge over the Cumberland River. In 1909, he entered the contracting construction field with the Foster-Creighton-Gould Company. While with that Company he handled many large bridge projects, including the substructure work on the bridge across the Ohio River, between Louisville, Ky., and New Albany, Ind.; The Louisville and Nashville Railroad Bridge over the Cumberland River, at Nashville; and the Apalachicola and Choctawatchee draw-bridge in Northern Florida.

Mr. Wilson became Vice-President of the Gould Contracting Company in 1915, and in 1917 he was elected President, which office he held until his retirement from active business in 1934. This Company was one of the outstanding builders of the South, and, under Mr. Wilson's supervision, constructed sixteen bridges over the Cumberland River, one of the most important of which was the $800 000 highway bridge between Nashville and Old Hickory, Tenn. The Company also built bridges for the Louisville and Nashville; the Nashville, Chattanooga, and St. Louis; and the Pennsylvania Railroad Companies. In addition, it constructed power plants, dams, and reinforced concrete buildings.

---

[1] Memoir prepared by Arthur J. Dyer, M. Am. Soc. C. E.

In 1903, Mr. Wilson was married to Maiella Byrns, of Nashville, sister of the late Speaker of the House of Representatives, Joseph W. Byrns. His widow and one daughter, Mary Elizabeth, survive him.

He was active in religious, fraternal, and civic circles in Nashville, having been an Elder in the Presbyterian Church, a Mason, a Shriner, a Son of the American Revolution, a member of the Rotary Club, and a member of the Chamber of Commerce. One honor of which Mr. Wilson was particularly proud was his life membership, attained by virtue of long membership, in the Society.

He was known everywhere as a man of high ideals and unswerving integrity. Never strong physically, he rose through his own efforts and ability to a place of highest respect in his profession.

Mr. Wilson was elected a Member of the American Society of Civil Engineers on December 2, 1903.

GEORGE LEVERETT WILSON, M. Am. Soc. C. E.[1]

Died April 1, 1939

The death of George Leverett Wilson on April 1, 1939, terminated an unusually long and useful engineering career. For fifty-six years he had been actively associated with the growth and development of the Northwest, and particularly with the development of transportation facilities in St. Paul, Minn., and Minneapolis, Minn., and the territory surrounding these two cities. At first he was associated with the building of railroads in Iowa, Minnesota, and the Dakotas, next with the construction of paved streets in St. Paul in the horse-and-buggy days, then with the development of many miles of bicycle paths in St. Paul in the nineties, and finally, for more than a third of a century, with the electric railway trackage in the Twin Cities and their suburbs. At the time of his death, Mr. Wilson was the oldest living past-president of both the Engineers Club of Minneapolis and the Engineering Society of St. Paul.

George Leverett Wilson was born at West Killingly, Conn., on February 14, 1855. He was the son of Seth A. and Ellen M. (Lee) Wilson. He was graduated from Sheffield Scientific School of Yale University, in New Haven,

---

[1] Memoir prepared by Frank S. Altman, Assoc. M. Am. Soc. C. E., and O. F. Moore, Engr., Maintenance of Way Dept., Twin City Lines, Minneapolis, Minn.

Conn., in 1877, taught school for two years, and spent one year in post-graduate study at Yale. He went west in 1880, and was employed as a Transitman and Resident Engineer in the Chicago, Rock Island and Pacific, the Chicago and Northwestern, and the Minneapolis and St. Louis Railway Companies. From 1881 to 1883, he was in charge of construction of the Devils Lake extension of the St. Paul, Minneapolis and Manitoba Railway (Great Northern). In 1884 he began his service with the City of St. Paul, first as an engineer with the water department, making surveys and constructing a masonry conduit for the new water supply for that city. The following year he was appointed Assistant City Engineer under the late L. W. Rundlett, M. Am. Soc. C. E., for many years City Engineer of St. Paul. He continued with the city engineering staff until 1903, holding the position of Chief Sewer Engineer during a great part of this period. Thus he had much to do with the engineering development of the city during its period of greatest growth.

In June, 1903, Mr. Wilson started work with the Twin City Rapid Transit Company as Engineer of Maintenance of Way, and remained with the street railway companies until his death. His active service ended June 1, 1936. During this time of service he supervised the construction and reconstruction of many miles of street railway tracks in Minnesota, including St. Paul, Minneapolis, South St. Paul, Stillwater, Lake Minnetonka, and White Bear Lake. Of the more permanent structures built under his supervision, the most notable is the Selby Hill tunnel in St. Paul, built in 1907. During Mr. Wilson's service with the company, the street railway system grew from 250 miles in 1903 to 524 miles of single track at the peak in 1931. This has been reduced since to 460 miles of single track.

Mr. Wilson was married to Fannie M. Scranton at Danielson, Conn., in 1884. One daughter, Ruth E. Wilson, was born to them.

Mr. Wilson was a thirty-second degree Scottish Rite Mason, a Knight Templar, a member of the Minneapolis Rotary Club, the Six O'Clock Club, the Engineers Club of Minneapolis, and the Engineers Society of St. Paul.

He was one of those rare individuals whom you meet far too seldom in the engineering profession—always friendly and sympathetic with younger members of the profession and held in the highest regard by associates and older fellow engineers.

Mr. Wilson was elected a Member of the American Society of Civil Engineers on February 5, 1890.

JOSEPH FRANKLIN WITMER, M. Am. Soc. C. E.[1]

DIED MAY 23, 1938

Joseph Franklin Witmer was born in Williamsville, N. Y., on November 25, 1859, the son of Tobias Witmer and Anna (Frick) Witmer. He received his early education in the public schools of Buffalo, N. Y., and was graduated from the New York State Normal School, at Buffalo. He then entered Bethany College, at Bethany, W. Va., from which he was graduated in 1884, with the degree of Bachelor of Arts. He received his engineering education at Rensselaer Polytechnic Institute, at Troy, N. Y., and was graduated in 1887, with the degree of Civil Engineer.

---

[1] Memoir prepared by C. W. Mower, Esq., Akron, Ohio.

From 1887 to 1890, Mr. Witmer engaged in the construction of water-works at Elgin and Sycamore, Ill., Mount Clemens, Mich., Rogers Park and La Grange, Ill., and an intake into Lake Michigan for the water-works of Escanaba, Mich. In this period he designed during the winter and superintended the construction in summer. He designed the water systems of Washington Heights, Ill., Ingersoll, Kincardine, London South, and Galt, Ont., Canada, and assisted in the preparation of the plans for the Peoria, Ill., Water-Works. In 1890, he was appointed Principal Assistant to the Chief Engineer, on the construction of water-works, at Seattle, Wash.; and, in 1891, he was made Resident Engineer in charge of construction of the water-works.

From 1892 to 1895, Mr. Witmer was a member of the firm of Vorhees and Witmer, Civil Engineers, with offices at Buffalo. During that period he served for a time as engineering member of the Civil Service Commission of the City of Buffalo, by appointment of the Mayor.

During the fifty-one years of his professional life, Mr. Witmer was identified with the design and construction of the water-works and sewerage systems serving four nations, nine States, and the Philippine Islands, and more than one hundred cities and communities. He designed and supervised the construction of water-works systems at Morris and Pana, Ill.; Greenfield, Tipton, Rochester, Columbia City, and La Grange, Ind.; Celina, Montpelier, and Ironton, Ohio; Dansville, Windsor, De Ruyter, Quogue (Long Island), Lima, Prattsburg, Clifton Springs, Suffern, Horseheads, Warsaw, Mexico, Naples, Perry, Craig, Epileptic Colony at Sonyea, the New York State Custodial Asylum, at Newark, N. Y.; Williamsville, Alden, Akron, Bolivar, Angelica, Silver Creek, Livonia, Caledonia, Allegany, Belfast, Cherry Creek, and Argola, N. Y.; and, at Cambridge Springs, Edenborn, Grove City, and Saegerstown, Pa.

His foreign engagements led Mr. Witmer to the Philippine Islands to make an estimate of the cost of the construction of a water-works and sewerage system for the City of Manila, and to Russia, for an English firm, to investigate and report on a proposed water-works system for Vladivostok, Siberia. In 1910, he was engaged by a London and Paris syndicate, to investigate and report on a project for supplying water to the City of Taltal, Chile, and for supplying the nitrate fields of Central Chile, with water from the Andes Mountains, through a conduit more than a hundred miles long. He investigated and made a comprehensive report for a New York Company on the sewerage project for Edmonton, Alberta, Canada.

Mr. Witmer was prominently identified with the engineering connected with the construction of the Buffalo and Williamsville Electric Railroad.

In evaluation and appraisal work, he established a national reputation, having appraised water-works systems for Jamestown, Salamanca, Corning, Medina, Suffern, Bolivar, Mount Morris, and Depew, N. Y.; Billings, Mont.; Meadville, Pa.; and the Huntington Water-Works, Huntington, W. Va.

Mr. Witmer was a member of the American Water Works Association. He was also a member of the following fraternities; Beta Theta Pi and Sigma Xi, and Ivy Lodge F. and A. M.

He was liberal in his views and noted for his fairness and ethical dealings in his engineering contact with others. He made and held many intimate associates throughout his life.

On October 8, 1924, Mr. Witmer was married to Minnie M. McCollom. He died in Elmira, N. Y., on May 23, 1938, and is survived by his widow.

Mr. Witmer was elected a Member of the American Society of Civil Engineers on May 4, 1904.

FRANK CHARLES WOLFE, M. Am. Soc. C. E.[1]

DIED APRIL 2, 1939

Frank Charles Wolfe was born at Union Bridge, Md., on December 7, 1870, the son of Daniel and Susan E. (Haines) Wolfe.

His education was begun in the public schools of Maryland, and was terminated by an engineering course at Cornell University, at Ithaca, N. Y., from which he was graduated in June, 1895, with the degree of Civil Engineer. For the years 1891 to 1895, inclusive, he was the winner of the Sibley Scholarship, an award made annually under a gift of the late Hiram Sibley for excellence of scholarship in the Engineering Schools of Cornell.

Shortly after his graduation, in 1895, Mr. Wolfe entered the employ of the American Bridge Company, at Chicago, Ill., as draftsman, and remained in that position until 1899, when he resigned, and entered the service of the Scherzer Rolling Lift Bridge Company, as designer, at Chicago. While thus employed he designed the foundations and superstructures for about one hundred movable lift bridges, with clear spans ranging in width from 20 ft to 160 ft.

In 1903 he became Assistant Bridge Engineer of the Chicago, Rock Island and Pacific Railway Company. During his four years of service with this line his duties comprised responsibility for the design of superstructure and substructures of all bridges built within the period concerned. In 1907 he was appointed Assistant Bridge Engineer of the Northern Pacific Railway Company, charged with the design of substructures and superstructures for all bridges. In 1909 he was offered the position of Chief Engineer, Maintenance of Way Department, for the Northern Pacific Railway Company, with headquarters at Denver, Colo., but, due to the death of Mrs. Wolfe and the special arrangements which he was forced to make with respect to his family, he was unable to accept this appointment. During 1909 he became associated with Mr. D. B. Banks, as structural expert, and, in that capacity, designed the power house for high pressure fire line for the City of Baltimore, Md.

---

[1] Memoir prepared by P. G. Lang, Jr., M. Am. Soc. C. E.

In 1911 Mr. Wolfe was appointed Bridge Engineer, Western Maryland Railway Company, with headquarters at Baltimore, and, during his two years' administration of that post, exercised responsible charge of the design and construction of all bridges involved in the project then under way between Cumberland, Md., and Connellsville, Pa. His duties also included supervision of bridge maintenance on the entire Western Maryland System, and water-front work, comprising piers, bulkheads, and transfer bridges.

He was appointed Chief Engineer of the McLean Contracting Company, of Baltimore, during 1913, and assumed charge of construction projects totaling about $1 000 000, including piers, bridges, dredging operations, and railroad construction. In 1915 he left the service of that firm to become Resident Engineer on the Stratford Avenue Bridge, Bridgeport, Conn., as representative of The J. E. Greiner Company, Consulting Engineers. In 1919 he resumed his post as Chief Engineer of the McLean Contracting Company, which he continued to administer until 1924. During this post-war period of five years he supervised projects totaling about $8 000 000, involving the Long Beach Bridge on Long Island, New York; the Western Maryland Railway Export Coal pier, at Baltimore; the Schuylkill River Bulkhead, Chestnut Street Pier, Substructure for Girard Pier 5, and Concrete Piling for Pier 84, Philadelphia, Pa.; and the South Street Bridge at Wilkes-Barre, Pa.

In 1924 Mr. Wolfe became Secretary-Treasurer and Chief Engineer for B. F. Johnson Company. After four years in this position he resigned and entered private practice as a Consulting Engineer, with headquarters at Baltimore. In that capacity his services were retained by H. K. Ferguson and Company, The Empire Construction Company of Baltimore, the Western Maryland Railway Company, the County of Nassau, New York, and others. For H. K. Ferguson and Company he designed and supervised the construction of the bulkhead at the plant of the Western Electric Company, at Baltimore; and for Nassau County, New York, he designed and supervised the prosecution of extensive repairs to the Long Beach Bridge and the construction of the Bayville Bridge. The termination of the latter project was nearly coincident with that of Mr. Wolfe's long and useful career, since the final papers were signed February 27, 1939, and his death occurred April 2 of that year.

On May 12, 1898, Mr. Wolfe was married to Wealthy Ann Burr, who died on February 1, 1909. The surviving children are Mrs. C. E. Whitmore, and Mrs. K. B. Pittinger. A son, Charles, was a Junior in the Engineering School at Cornell University, when he was drowned in the Delaware River, Philadelphia, in January, 1923.

Mr. Wolfe was a member of the Engineers Club and the Press Club of Baltimore, and of the Cornell Club, of New York, N. Y.

Mr. Wolfe was elected a Member of the American Society of Civil Engineers on January 31, 1911.

CARMI IRVING BAUSHER, Assoc. M. Am. Soc. C. E.[1]

DIED DECEMBER 5, 1938

Carmi Irving Bausher was born in Reading, Pa., on November 14, 1869, a son of DeWalt P. Bausher and Ellen M. Bausher. He was graduated from the Reading High School in June, 1888, and from that time until 1896 was employed as a Structural Draftsman by Coffrode and Saylor, of Pottstown, Pa.; Phoenix Bridge Company, of Phoenixville, Pa.; the Reading Rolling Mill Company; and the Elmira (N. Y.) Bridge Company.

From 1896 until his retirement on August 1, 1932, he was employed by the Pennsylvania Steel Company, in the Bridge and Construction Department, at Steelton, Pa., and finally with the Fabricated Steel Construction Department of the Bethlehem Steel Company, Bethlehem, Pa.

He became a skilled draftsman and engineer of wide experience in structural steel work, his services having been employed in such capacity in connection with buildings and bridges of all types, among which the following structures are particularly outstanding: Double-Track, Double-Leaf Scherzer Rolling Lift Bridge over Taylor Street, Chicago, Ill.; the Williamsburg and the Queensboro bridges over the East River, New York, N. Y.; the Harahan Bridge over the Mississippi River at Memphis, Tenn.; and the Lakehurst Hangar, Lakehurst, N. J.

Mr. Bausher possessed the ability to conceive the requirements from the engineering standpoint, and to apply thereto the knowledge obtained from years of close association with shop practice. He was interested to a marked degree in the training of the younger draftsmen and engineers who knew him as a friend to whom they could turn at all times for counsel and guidance in engineering matters with the confidence that his advice would be given cheerfully in a most helpful and constructive manner.

He was married to Bertha Virginia Lindecukle on June 28, 1894, and is survived by his widow and two sons, George Irving and Richard Vastine.

Mr. Bausher was elected an Associate Member of the American Society of Civil Engineers on December 7, 1898.

JOHN ALLEYNE CALHOUN BOGART, Assoc. M. Am. Soc. C. E.[1]

DIED MARCH 1, 1939

John Alleyne Calhoun Bogart was born in Savannah, Ga., on July 15, 1904. His Canadian father, a sea captain running into Savannah, retired soon after John's birth on account of his wife's health, and the family moved to New Brunswick, Canada. The father took part in the development of the western provinces of Canada, at one time raising wheat in Saskatchewan. As a high school student in Edmonton, Alberta, John was active as a Boy Scout, reaching the rank of Rover. His family removed to Victoria, British Columbia, about 1928, where his mother, Henrietta (Calhoun) Bogart, still lives (1939).

---

[1] Memoir prepared by Charles H Mercer, M. Am. Soc. C. E.

[1] Memoir prepared by Charles Carroll Brown, M. Am. Soc. C. E.

The presence of an uncle, Captain William D. Bogart, doubtless aided John to make Florida his home. In Tampa, Fla., his employment by an engineer in laying out a large subdivision was the persuasive factor in his becoming a civil engineer, and he entered the University of Florida, at Gainesville, as a special student until he completed his high school work. With some aid from his uncle during the first two years of college work he sustained himself as working students do, usually, and by acting as an undertaker's assistant.

On December 29, 1929, he was married to Ruby Knight, of Florida, who was of great assistance to him during his undergraduate days and his brief practice of Civil Engineering.

He received the degree of Bachelor of Science in Civil Engineering in 1931. With the aid of a position as graduate assistant, and with employment in research work on the new sewage treatment plant at the University, and on the construction and early operation of the new sewage treatment plant of Gainesville, he was able to continue his studies and practical application of them and to earn the University degree of Master of Science in Civil Engineering in 1933, and that of Civil Engineer in 1934.

In 1933 and 1934, as a member of the firm of Brown and Bogart, he was engaged in developing methods of operation of the new sewage treatment plant at Gainesville, in the design of a new sewage treatment plant for Tallahassee, Fla., and in formulating satisfactory methods of operating the three plants mentioned. The firm of Brown and Bogart also prepared several plans for water supplies for small cities and towns in Florida, which extended his practice into that field. The financial abilities of the municipalities did not prove equal to the requirements of Public Works Administration (PWA), and Mr. Bogart took a position as Director of Operation in Bradford County, Florida, under Emergency Relief Administration (ERA) and Civil Works Administration (CWA), and later in Hillsborough and Walton Counties. In 1935 he designed water and sewage collection and distribution systems for Key West, Fla., under relief agencies, followed by supervision of the work until it was intermitted. In May, 1936, he received an appointment as Lieutenant (jg) C.E., USNR. He worked as Assistant Engineer at the Navy Yard in Charleston, S. C., in charge of extensive mosquito control work and as hydraulic engineer compiling data regarding the feasibility of the Santee-Cooper River canal.

On October 1, 1937, he was appointed City Manager, Auditor, and Clerk of the City of Fernandina, Fla. During his term of office municipal highway improvements amounting to $15 000 were completed, an $80 000 municipal dock was constructed under PWA, and a PWA mosquito control project was begun. Many changes in municipal procedure and policy were instituted under his administration.

Mr. Bogart's illness developed during this period and culminated on March 1, 1939, at the residence of his aunt, Mrs. Ida Bogart, in Fernandina.

John A. C. Bogart was a keen student, a careful worker, an enthusiastic research worker, and an honest man, constant in upholding the ethical principles of the engineering profession. Notwithstanding the broken nature of his early education, he developed rapidly when he made his choice of a profession, acquiring the methods of study, observation, and self-education in the University of Florida which showed his innate ability to find the important ideas behind any work in which he was engaged, and to develop effective methods of gathering information and using it in making practical solutions of problems confronting him. His most promising career was cut short in its beginning with undoubted loss to the engineering profession and its practice.

Mr. Bogart was christened in the Protestant Episcopal Church, and was a member of the Christian Science Society, at Gainesville.

His immediate relatives at his death were his wife, Ruby Knight Bogart, his mother, Mrs. Frank C. Bogart, a brother, Charles F. Bogart, and two sisters, Mrs. Ian McGavin and Miss Rachael Bogart.

John A. C. Bogart was a member of the Student Chapter, American Society of Civil Engineers, in the University of Florida, and was admitted as a Junior after his graduation on October 26, 1931. He was elected an Associate Member on January 14, 1936.

FORREST McKENDREE CASEY, Assoc. M. Am. Soc. C. E.[1]

DIED MARCH 19, 1938

Forrest McKendree Casey was born on October 27, 1884, in Oak Harbor, Ohio. His parents were McKendree A. and Clara E. (Rowe) Casey, of Toledo, Ohio. He attended the Grammar and High Schools in Toledo, and the John B. Stetson University, at DeLand, Fla.

From 1906 to 1909, Mr. Casey was employed as Draftsman in the Office of the City Engineer of Seattle, Wash., where he designed plans for paving, sewers, and street extensions. From 1910 to 1918 (except as noted subsequently), he was employed as Draftsman, and after May 16, 1916, as Assistant Engineer, by the City Engineer of Los Angeles, Calif., in designing storm drains, making paving and street plans, as well as studies and reports on drainage.

On July 1, 1916, Mr. Casey was one of the organizers of a new regiment of Coast Artillery in the National Guard of California, and enlisted in that regiment as a Private in the 15th Company. Six days after war was declared with Germany, in 1917, this regiment was called into Federal service and entrained immediately for Fort Rosecrans, San Diego, Calif. On July 1,

---

[1] Memoir prepared by W. T. Knowlton, M. Am. Soc. C. E.

1917, Mr. Casey's hearing was impaired, and he was given a discharge from the United States Army for disability.

From June, 1918, to June, 1921, he was employed by the General Petroleum Corporation of Los Angeles, at its Vernon, Calif., refinery, in the design of apparatus, structures, and pump-houses, and in the standardizing of field equipment. From July, 1921, to June, 1923, he served as Junior Designer in the Engineering Department of the Southern California Edison Corporation, working in its hydro-electric power plant on general hydraulic and structural design, also plant assembly and penstock calculations, and studies of surge tanks and tunnels, as well as the design of special tunneling machines and equipment for testing materials.

From June, 1923, until his death on March 19, 1938, Mr. Casey was again employed by the City Engineer of Los Angeles as Junior Civil Engineer on storm-drain design, and general engineering computations and estimates. From August 16, 1924, he served as Assistant Engineer in charge of storm drain design and was responsible for the solution of construction difficulties and changes in design and detail.

He was a member of the Sunshine Post No. 251 of the American Legion from the time of its organization, and at his death he was a member of the Executive Committee and Historian of this Post. He was also a member of the Clarence F. Smith Masonic Lodge.

Mr. Casey was always interested in helping young engineers by passing on to them those things which he had learned by experience and hard work, even if, later, it might prove to his own disadvantage. He was happy to have lived to see the Engineering Profession take its rightful place in the business and professional world. Although never rugged in physique, he had a clear sense of humor and had many interests in life. Among his several hobbies he enjoyed fencing most of all.

He was married on June 29, 1907, to Helen Fahs, in Renton, Wash., who survives him, together with his brother, Cranston A. Casey.

Mr. Casey was elected an Associate Member of the American Society of Civil Engineers on May 25, 1931.

JOHN ANTHONY CROOK, Assoc. M. Am. Soc. C. E.[1]

Died August 9, 1937

John Anthony Crook was born on April 9, 1879, at Falls City, Nebr., and was the eldest child of William Hampton Crook and Lydia (Worley) Crook.

His earlier education was received in the public schools at Falls City. After graduating from the high school, he attended the University of Nebraska at Lincoln, Nebr., where he studied engineering.

He began engineering work in 1897 as estimator, designer, and contracting engineer in the Omaha (Nebraska) Office of the Canton Bridge Company, which was engaged in the building of highway and railway bridges. He remained in this position until 1900 when he became associated with the John Gilligan Company of Falls City as Chief Engineer and Secretary of the Company, which was engaged in general contracting and engineering work in connection with the design and construction of public works.

---

[1] Memoir prepared by Oliver W. Childs, M. Am. Soc. C. E.

Concurrently with other work, Mr. Crook was County Engineer of Richardson County, Nebraska, from 1903 to 1910, and was City Engineer of Falls City from 1908 to 1912.

In 1908 he organized the Monarch Engineering Company of Falls City and engaged in the practice of civil engineering and in general contracting. This business was developed and extended, with branch offices in Kansas City, Mo., Oklahoma City, Okla., and Denver, Colo., and included the designing and construction of bridges, buildings, roads, pavements, sewers, water-works, and public improvement in general. As the business developed mainly along the lines of bridges and buildings, structural steel was an important item, and in 1916 Mr. Crook acquired a structural steel shop in Denver, and started the operation of the Denver Steel and Iron Works Company as a structural steel fabricating plant. At this time he moved to Denver and continued to reside there and to operate the two associated companies until his death.

When reinforced concrete came into use, Mr. Crook spent considerable time investigating the design and use of concrete as a structural material and studying the comparative value of concrete and steel construction. He became a firm believer in the superiority of steel construction and was very active in advocating and promoting its use in preference to concrete. He was among the first to use steel piles for foundations and made use of them in a large number of highway bridges before they were generally recognized by engineers as legitimate and economical construction.

In addition to his work in engineering and contracting, Mr. Crook had many and varied interests, among which were livestock raising and farming. He owned a number of farms, among which was the Pine Bar Ranch near Denver, to which he paid particular attention. He installed all modern improvements necessary to make it a model ranch, and raised pedigreed stock according to the most approved practice. He also owned or was interested in the operation of a number of mines. He took an active interest in public affairs, but was not a political partisan.

Mr. Crook had unusual ability as a public speaker, and could be depended on to make an interesting address on any subject in which he was interested, or on any subject of current public interest, whenever there was occasion to do so.

His various business interests did not prevent him from being a reader and student. He studied carefully any subject that interested him, analyzing it before making conclusions, and was able to give reasons in support of his ideas. He was a Mason, a Shriner, an Elk, and a member of the Denver Athletic Club. His religious affiliations were with the Protestant Episcopal Church.

In addition to his engineering training and experience, he had a proper balance of other information, which enabled him to consider matters from their various viewpoints and qualified him as a successful financier and business executive.

He was married on June 4, 1899, to Minnie Dalbey of Coin, Iowa, at Chillicothe, Mo., and is survived by his widow and a daughter, Constance Crook Ambrose.

Mr. Crook was elected a Junior of the American Society of Civil Engineers on February 3, 1903, and an Associate Member on December 1, 1908.

NOAH CUMMINGS, Assoc. M. Am. Soc. C. E.[1]

DIED FEBRUARY 13, 1939

Noah Cummings, the son of James Daniel Cummings and Nancy Ransom (Hubbell) Cummings, was born in Middlefield, Otsego County, New York, on January 14, 1874. On his mother's side he traced his ancestry to Richard Hubbell, born in 1628 in Great Britain, who emigrated to Connecticut in 1648, and to Robert Ransom who emigrated from Kent, England, to Massachusetts in 1654. Thomas Ransom, fifth in line from Robert, served his country in the Revolutionary War. Mr. Cummings was one of the few remaining Americans to be born in a log cabin. He was the fourth of six children. His parents were poor struggling farmers, and early in life he helped in the simpler duties on the farm. At the age of six he learned to milk cows and at eight he was driving horses.

He began his schooling in a one-room, one-teacher school and during that period, at the age of seven, his seventeen year old teacher told him: "You know more arithmetic than I do."

When he was ten years old his parents were living on a farm 3 miles from Schenevus, N. Y., and Noah had the opportunity to enter the High School in that village. He walked the 3 miles to and from the school in all kinds of weather. In that school he completed his grade school as well as his high school subjects and made such progress that he graduated at the age of fourteen.

He had decided on an engineering course at Cornell University, at Ithaca, N. Y., but was confronted with a minimum 16-yr age requirement. He spent the next two years taking post-graduate work at the Schenevus High School to such good advantage that he not only secured a State Scholarship, which provided his tuition at Cornell, but also passed a highly competitive examination at the University which entitled him to the John Stanton Gould Scholarship in mathematics, which he held during his four years at the University. It is evidence of high scholarship that he was elected to the Sigma Xi Society in his Senior year.

---

[1] Memoir prepared by a Committee of the Metropolitan Section consisting of Thomas S. Clark, Reginald H. Keays, John A. Knighton, Members, Am. Soc. C. E., and Isidore Delson, Assoc. M. Am. Soc. C. E.

Although he had a keen sense of humor and was an excellent companion, he always held to the serious things of life. During his college days he was a member of the Cornell University Christian Association, Secretary of Section B of the Mathematical Club, Class Treasurer during his Junior year, and Chief Engineer of the Senior and Junior classes engaged in geodetic surveys in his Senior year. He was graduated in 1894 with the degree of Civil Engineer.

One of his classmates says of him: "At college every one looked up to him, not only for his ability, clear brain and brilliancy in his engineering courses, but for his really lovable nature."

Like most young engineers, Mr. Cummings found employment in several minor capacities before entering upon what was to prove his final life work.

From July, 1894, to April, 1895, he was employed by the Aqueduct Commission of the City of New York, first under the title of Laborer and then as Axeman. It was while thus engaged that he met the late Robert Ridgway, Past-President and Hon. M. Am. Soc. C. E., and there began a friendship that lasted until Mr. Ridgway's death.

From April, 1895, to April, 1896, Mr. Cummings was employed by J. W. Hoffman and Company, Contractors, on the foundations for a steel highway bridge over the Delaware River between Easton, Pa., and Phillipsburg, N. J., and on a dam for the water supply of Cold Spring, N. Y.

In April, 1896, he began working for the City of New York and continued in such employ until his death. From the time he entered the City's service until August, 1901, he was employed as Transitman and Computer and later as Assistant Engineer in the Topographical Bureau of the Board of Public Improvements in the Bronx.

Although his connections with that Board were not severed, Mr. Cummings was absent during the Spanish-American War. In June, 1898, he enlisted as a Private in the First United States Volunteer Engineers, Company C, and saw service in Puerto Rico. The peace protocol was signed while the regiment was en route to Puerto Rico so that he had little actual military service. One of his comrades relates that about one week after arrival, tents were pitched alongside the Rio Portuguesa near Ponce and he and Noah were assigned to take cross-sections of the river opposite the camp. The site of the camp was unusual in that the alluvial plain alongside the river was somewhat higher than the camp ground back of it and some of the officers conceived the idea of cutting drainage ditches perpendicular to the river to drain the ground back of the camp. This was done. The river was a mere trickle and the sun was shining, so the surveyors discarded much of their clothing and were wading in the river-bed when word came from up stream that a flood was on its way. Soon a wave came foaming down the river like a wall of water. The channel was immediately filled to the top of the banks, also the lateral ditches, flooding the back of the camp. The ditches were then stopped up as well as possible with bales of hay. Those who knew Noah Cummings can almost hear the characteristic, "Oh, my gosh," and the familiar laugh, as the waters came rushing down.

Private Cummings received his honorable discharge in 1899, but like so many others he returned to the United States with health impaired and it was some months before he was able to resume his duties with the Board of Public Improvements in the Bronx.

On August 1, 1901, Mr. Cummings entered the Department of Bridges as Bridge Draftsman. At that time plans were being developed for Bridges No. 3 and No. 4, later known as the Manhattan and Queensboro Bridges. Mr. Cummings' first work was on the plans of Bridge No. 4. He advanced to the grade of Assistant Engineer and for several years was in charge of surveys for the Department.

In 1916 the Department of Bridges became the Department of Plant and Structures. Some time before that Mr. Cummings was brought into the Chief Engineer's office where he was to remain so many years. There, in his contacts with other departments, he acquired a knowledge of city government surpassed by few.

In 1935 he became Deputy Chief Engineer of the Department of Plant and Structures with increased responsibilities. Much of the official correspondence of the Department went through his hands. In preparing a reply to an unfair or a bitter communication his answer would be courteous. Often he would say: "A soft answer turneth away wrath." On January 1, 1938, when the revised New York City Charter became effective, the functions of the Department of Plant and Structures, other than the ferry service, were taken over by the new Department of Public Works. As the Department was finally organized on July 1, 1938, the Bureau of Bridges was established which virtually embraced the functions of the old Department of Plant and Structures.

The merits of Mr. Cummings, his character and his personality, had deeply impressed the Commissioner and the Chief Engineer of the new department and accordingly he was appointed Director of the Bureau of Bridges, a choice which was received with the utmost gratification by his associates in the service.

With characteristic modesty, tact, and kindliness, Mr. Cummings assumed his new responsibilities. It was not long, however, before sickness attacked him. The conscientious and faithful civil servant chafed under inaction and could not reconcile himself to illness and prolonged absence from duty. Always, he had been on the job. His associates who loved him, anxiously waited and devoutly hoped, but the end finally came, swiftly and mercifully.

Mr. Cummings was a Charter Member of the Municipal Engineers of the City of New York. He was successively, Member of the Finance Committee, Director, Vice-President, and in 1928 was President of that Society. He was also a member of Bunting Lodge, Free and Accepted Masons of New York City.

In his religion, Mr. Cummings was a Unitarian. He was a member and a Trustee of the First Liberal Church of Mount Vernon, N. Y. He took an active part in that church, and supported it generously.

Mr. Cummings was married on January 9, 1907, to Louise Lerch who died on December 16, 1935. The passing of the "Madam" as he was wont to call her, deeply affected him, and saddened his later days.

He is survived by his mother, a son George, a grandson Gifford, and by two brothers, Lee Herbert and Howard Raymond.

Mr. Cummings was elected a Junior of the American Society of Civil Engineers on March 3, 1896, and an Associate Member on January 6, 1904.

CLARENCE DERRICK, Assoc. M. Am. Soc. C. E.[1]

Died March 20, 1938

Clarence Derrick was born on September 7, 1881, at Halifax, Va., the son of Henry Clay and Martha (Cosby) Derrick. His father, the late Henry Clay Derrick, M. Am. Soc. C. E., was prominently identified with railroad construction in the South between the years 1851 and 1888. He also had a distinguished military career as Captain of Engineers in the Confederate Army and, later, as Lieutenant Colonel of Engineers in the service of the Khedive of Egypt.

Clarence Derrick was graduated from the Virginia Polytechnic Institute, at Blacksburg, Va., in 1901, with the degree of Bachelor of Science in Mechanical Engineering. Later, he spent a year, 1904–1905, at Lehigh University, at Bethlehem, Pa., under the late Mansfield Merriman, M. Am. Soc. C. E., in the study of structural design.

His first engineering work was with the American Bridge Company, at Trenton, N. J. Until 1908, he had a varied engineering experience, principally in railway bridge design, having been associated, successively, with the Rock Island Railroad Company, in Chicago, Ill.; the Massillon Bridge Company, in Massillon, Ohio; the Carolina, Clinchfield and Ohio Railroad Company, at Bristol, Tenn.; and the Virginian Railway Company, at Norfolk, Va. In 1907, he was employed by the Pulaski Mining Company, on surveys of its extensive properties in Southwestern Virginia.

In 1908, Mr. Derrick became associated with the Isthmian Canal Commission in connection with the design of the emergency dams for the Panama Canal. This work was under the general direction of Henry Goldmark, M. Am. Soc. C. E., and Mr. Derrick was associated at Washington, D. C., with David A. Molitor, M. Am. Soc. C. E., and, later, at the Canal Zone with T. B. Mönniche, M. Am. Soc. C. E., in developing the highly complicated design for these structures.

In 1911 Mr. Derrick accepted a position as Engineer in Structural Steel Design with The Berlin Construction Company, Incorporated, at Berlin, Conn., and retained this connection until his death. He made his home in the near-by city of New Britain, Conn. He brought to this organization a well-grounded experience, and many New England structures bear silent testimony to the skill of this son of the South.

---

[1] Memoir prepared by Charles F. Chase, M. Am. Soc. C. E., and G. B. Taylor, Assoc. M. Am. Soc. C. E.

In the days when the cities and towns, State Highway Departments and electrical railways, and even the railroads, sought assistance in their bridge problems, the construction company's engineer enjoyed a wide range of experience, and, in this field, Mr. Derrick labored with both technical skill and common sense, rarely, however, with personal recognition.

In later years, he encountered the variety of design inherent in modern industrial operations, solving his problems with unfailing ingenuity until ill health forced his partial retirement in 1935.

He was rather shy in manner at first acquaintance, not given to self-assertion, content to let his work speak. When one enjoyed his confidence, he proved a capable and humorous story-teller, drawing on his Military School life, his Canal Zone experience, and his keen faculty for detailed observation. He had musical talent, with the flute for its outlet, and a bent for caricature that was difficult to suppress, making the victims among his associates assert that an artist was lost in this engineer.

Mr. Derrick was married to Eva Reid, of Trenton, N. J., who died in 1934. He is survived by two sons, H. Reid Derrick and Clarence Derrick, Jr.; a sister, Cornelia C. Derrick; and a brother, G. H. Derrick, M. Am. Soc. C. E.

He died on March 20, 1938, after a rather long illness, at the Gaylord Farm Sanatorium, at Wallingford, Conn., and was buried in Trenton, N. J.

On the top of Talcott Mountain, at Avon, Conn., west of Hartford, Conn., stands the beautiful Heublein Tower, overlooking the valley of the Farmington River. The tower is visible for miles from the College Highway running north from New Haven, Conn., to Northampton, Mass. The invisible foundations and framework which enable this structure to stand steadfast in its exposed situation were designed by Clarence Derrick. His friends in Connecticut will remember him as they pass this tower. It typifies his hidden strength.

Mr. Derrick was elected an Associate Member of the American Society of Civil Engineers on October 4, 1910.

JOHN LESLIE DOBBINS, Assoc. M. Am. Soc. C. E.[1]

DIED JULY 25, 1938

John Leslie Dobbins was born on September 6, 1883, at Calistoga, Calif. He was the son of the Reverend Hugh Hillis Dobbins, a Congregational Minister, and Mary Eloise (Trowbridge) Dobbins. He was the youngest of the family, and had several older sisters.

---

[1] Memoir prepared by Ned D. Baker, M. Am. Soc. C. E.

His father was one of the early pioneer missionaries of the West, and young Dobbins was reared in the religious atmosphere of a minister's home. He became affiliated with the Presbyterian Church as a young lad, and was a member until the time of his death.

He was graduated from the University of California, at Berkeley, Calif., with the degree of Bachelor of Arts in Letters in 1905. Not content with an academic education, he continued his studies and received his Bachelor of Science degree in Civil Engineering in 1907.

Mr. Dobbins then spent two years in railroad and mining work in Nevada. In 1909 he went to China to become Professor of Railway Engineering at the Imperial Pei Yang University at Tientsin, a position which he held for three and one-half years.

It was during this time in China that Mr. Dobbins first recognized the commercial possibilities of oriental trade, which led him later to organize several companies for that purpose.

In 1913 he returned to the States, and for a year engaged in engineering work in San Francisco, Calif., principally on flood control and irrigation work.

About this time he was married to Natalia Potter, who survives him together with their two sons, John Potter and David Trowbridge.

Mr. Dobbins took his bride back to China where he resumed his teaching, for another three years, as head of the Engineering Department of Pei Yang University at Tientsin. For a time he was also Chief Engineer of the Yunnan Szechuan and Tengyueh Railway Company.

While in China Mr. Dobbins organized and operated the American Machinery and Export Company, carrying on trade between America and China and other Far Eastern countries. Returning to San Francisco early in 1917, he remained in this company as Vice-President and General Manager.

Mr. Dobbins also widened his interest in the oriental trade by becoming a Vice-President and Member of the Board of Directors of the Koster Company of San Francisco. In this capacity, his engineering training and intimate knowledge of China were of great value in solving the many problems in packaging and shipping unusual commodities.

From 1921 to 1928, he conducted offices as Consulting Engineer in New York City and San Francisco, specializing in development, organization, and operation of hydro-electric and mining projects.

The following years Mr. Dobbins served as official and director of numerous successful enterprises. One such, of more than ordinary interest, was the Anchorage Light and Power Company, of Anchorage, Alaska, said to be the most northerly hydro-electric plant on the American Continent. This project was conceived, organized, financed, and constructed under Mr. Dobbins' guidance while he was engaged in mining developments around Anchorage.

For several years prior to his death, Mr. Dobbins had maintained his office in San Francisco, but he was not very active in the practice of Engineering. His interests were largely in connection with companies that he had been instrumental in organizing, and in which he had served as officer or on the Board of Directors.

His chief recreations were golf, chess, and tennis, in all of which he was better than the average. He traveled extensively, both in connection with his profession, and for pleasure.

He was actively engaged in enlisting sympathy and means for relief for the unfortunate victims of the undeclared war in China. At the time of his death he was a member of the East Bay Committee of the Associated Boards for Christian Colleges in China.

He was a member of the Sigma Xi and Tau Beta Pi Societies, the American Railway Engineers Association, the Olympic Club of San Francisco, the Faculty Club of the University of California, and the St. John's Presbyterian Church of Berkeley.

Mr. Dobbins was elected an Associate Member of the American Society of Civil Engineers on May 28, 1912.

CHARLES HENRY FARNHAM, Assoc. M. Am. Soc. C. E.[1]

Died June 11, 1938

Charles Henry Farnham was born in Newburg, Me., on January 16, 1875. He was the son of Walter and Mary (Kilham) Farnham. He received his early education in the public schools of Beverly, Mass., and, later, attended the University of Maine, at Orono, Me., from which he was graduated in 1897, with the degree of Bachelor of Civil Engineering. During his college years he worked as Rodman and Leveler on different land surveys, and also on the construction of the Bangor, Orono, and Old Town Electric Railway.

In 1898, at the outbreak of the Spanish-American War, Mr. Farnham was appointed a First Lieutenant of the 8th Massachusetts Volunteer Infantry, and was detailed as Assistant to the Division Engineer, 3d Division, First Army Corps. In that year he had charge of road construction at Chickamauga Park, Georgia, and camp construction at Lexington, Ky., and Americus, Ga.

At the close of the Spanish-American War, he was appointed Resident Engineer of the Massachusetts Highway Commission, engaged in construction work at Haverhill and Attleboro, Mass., and in office work at Boston, Mass.

In 1900 and 1901, Mr. Farnham was with the Isthmian Canal Commission, as Assistant Engineer in charge of the Test Boring Division, in Nicaragua. The work included test borings for estimates and foundations for locks and dams; and office work in Washington, D. C.

He was engaged as Provincial Supervisor for the Philippine Islands, in 1901, and was assigned to the Province of Bulacan in charge of road and bridge construction and repair. In 1902 he served as Assistant Engineer in the Department of Public Works, of Manila, in charge of streets, and the building of a new stone-crushing plant at Talim Island, Laguna de Bay, Philippine Islands.

---

[1] Memoir prepared from data supplied by the family and on file at the Headquarters of the Society.

Mr. Farnham went to China in 1902, to work on the Canton-Hankow Railway as Resident Engineer on the Sam-shui Division; later, he was in charge of the final location and field work between Canton and Fat Shan; and afterward became Division Engineer of the Sam-shui Division. This Division included twenty-two steel bridges, two concrete arch culverts, four concrete box culverts, thirty-two iron pipe culverts, and the work was completed at an estimated cost of $1 000 000. He returned to the Philippine Islands in 1906, and was employed as Division Engineer by the Philippine Railway Company. He had entire charge of the construction and operation of the railroad, including bridges and stations, on the Island of Cebu.

After the completion of the railroad in Cebu Mr. Farnham had charge of the construction of an electric street railway in Birmingham, Ala., and also worked on an electric tramway in Pernambuco, Brazil. When this work was completed he gave up foreign engagements and went into the constructing business in Boston. In 1919, he became Assistant Superintendent of a Boys Industrial School, in Shirley, Mass., and Supervisor of Construction of the three Industrial Schools of Massachusetts. He retired to private life in 1935.

Mr. Farnham was a man of sterling character, quiet, conscientious, modest, and of the highest integrity, with an outstanding quality of loyalty.

He was a member of Alpha Tau Omega Fraternity. While at the University of Maine, he, with two other students, originated an honor society called Lambda Sigma Eta. In 1900, when it became a National Society, this name was changed to Phi Kappa Phi. It has now more than fifty Chapters, and is established in some of the leading universities of the United States.

He is survived by his widow, Florence (Merrill) Farnham, to whom he was married in Manila, in 1906.

Mr. Farnham was elected an Associate Member of the American Society of Civil Engineers on June 1, 1904.

MILO CLINTON HALSEY, Assoc. M. Am. Soc. C. E.[1]

DIED MAY 12, 1939

Milo Clinton Halsey was born at Lewis, Iowa, on August 24, 1881. His father was George Clinton Halsey, and his mother, Grace Ellen (Morphy) Halsey, both of whom were natives of New York, but whose families moved to Iowa at an early date. George Clinton Halsey was a general building contractor, and it was this fact which largely influenced his son in deciding upon structural engineering as his life's work.

Mr. Halsey's parents were among the Iowans who elected to settle in Southern California, which they did when Milo was but two years of age;

---

[1] Memoir prepared by C. K. Bowen, Assistant to President, Pacific Electric Ry., Los Angeles, Calif.

and, since practically all his life was spent in or near Los Angeles, he could almost qualify as a "Native Son." He received his early education in the public schools, and was graduated from the Los Angeles High School.

He began his practical engineering experience as Rodman and Chainman for the East Whittier Land and Water Company in March, 1902, and by June, 1903, had been advanced to Foreman in charge of construction. Determined to obtain a scientific approach to what he had now decided upon as a career, young Halsey entered Stanford University, at Stanford University, Calif., in August, 1904, as a special student in Civil Engineering, and so continued until April, 1906, spending his summer vacation periods in building construction jobs; thus he put into practice the theories he had acquired in the class room.

The period from May, 1906, until August, 1908, was spent by Mr. Halsey in the service of various building contractors and architects in the design and erection of steel and reinforced concrete buildings, and, since the latter type was just beginning to prove a serious rival of the older type of steel frame construction, many problems, new to the building engineer, had to be considered and overcome. It was in this phase of engineering that this rising young engineer first showed the aptitude, courage, and resourcefulness which at a later period was so dominant a characteristic of his life and of his life's work.

In June, 1909, Mr. Halsey entered Massachusetts Institute of Technology, at Boston, Mass., for a year of advanced work in structural engineering, and upon completion of the course, returned to California where he re-entered the field of reinforced concrete construction, serving as Supervising Engineer in the design and erection of various buildings for the firm of Richards-Neustadt Construction Company, as well as for other contractors in the same field.

It was in December, 1910, that Mr. Halsey was appointed to the position of Chief Structural Draftsman, in the office of the Chief Engineer, Pacific Electric Railway Company, and thus formed a connection that was to endure to the end of his life. During this entire time, it was the writer's privilege to have been his close personal friend and professional associate.

An early recognition of his exceptional engineering ability led to his promotion in April, 1911, to the position of Structural Engineer of this rapidly expanding electric interurban railway system, and this position he held until his death. Various duties were added to his position, so that for many years, he not only supervised the design and construction of all buildings, bridges, elevated structures, subways and the like, but also had charge of their maintenance, reporting directly to the Chief Engineer.

A complete list of the various structures which Mr. Halsey designed and constructed for this railroad during his twenty-eight years of service would be too lengthy to include herein. A few of the more important (the cost of which totals millions of dollars) would include the Company's main shops, covering 125 acres at Torrance, Calif.; the Los Angeles-Glendale-Hollywood Subway; elevated tracts serving the main Los Angeles Station; Subway Terminal Station; grade-separation structures at Pico Boulevard, Roosevelt Highway, La Cienega Boulevard, Firestone Boulevard, Mission Boulevard, and at many other points, and dozens of sub-stations, passenger and freight stations, bridges, drainage structures, etc.

Personally, Milo Halsey was a kindly, generous, considerate gentleman—a man who merited, won, and retained the love of family, friends, and professional associates. Uncompromisingly honest, he was at all times just, and he never asked a subordinate to do that which he, himself, was not willing and ready to do twice over.

In 1907, Mr. Halsey was married to Mary Cosette Dorland, daughter of the Reverend Chester Paul Dorland, a prominent Congregational minister. Mr. Halsey was, himself, a member of that Church. He is survived by his widow, two daughters, a son, and two grandchildren.

He was also a member of the Structural Engineers Association of Southern California, and in 1936–1937 was Treasurer of the Los Angeles Section, American Society of Civil Engineers.

Mr. Halsey was elected a Junior of the American Society of Civil Engineers on June 30, 1910, and an Associate Member on June 4, 1913.

SAMUEL ALEXANDER HART, Assoc. M. Am. Soc. C. E.[1]

Died March 20, 1938

Early on Sunday morning, March 20, 1938, Samuel Alexander Hart succumbed to the ravages of a long illness at his home in Sacramento, Calif. Although in poor health for a number of years, he had continued his duties in the Office of the State Engineer as Senior Engineer, Supervision of Dams, until less than three weeks before his death.

The son of Henry Eldredge and Anzolette (Hayward) Hart, Samuel Alexander Hart was born at Stockbridge, Wis., on December 14, 1885, where he received his early education. In 1903, he went to California where he completed his preparation for college, entering the University of California, at Berkeley, Calif., with the Class of 1910, but the necessities of self-support prevented his graduation until 1911, when he received his Bachelor of Science degree.

Although he was graduated in mining, Mr. Hart chose to follow irrigation and hydraulic engineering, and devoted the major part of his professional career to these two branches. The first year after leaving college he spent in various capacities on surveys and construction in California and Arizona. From June, 1912, until May, 1915, he served as Chief Engineer of the Waterford Irrigation District, at Waterford, Calif., leaving that work to assume the position of Assistant Engineer with the South San Joaquin (Calif.) Irrigation District where he was employed on the investigation of a mountain water supply and on the construction of the Woodward Dam, a large hydraulic-fill structure.

Mr. Hart served in the World War from August, 1917, until June, 1919, and during the following year he was engaged in private business. From

---

[1] Memoir prepared by a Committee of the Sacramento Section consisting of W. A. Perkins, M. Am. Soc. C. E., and G. F. Engle, Assoc. M. Am. Soc. C. E.

July, 1920, until October, 1921, he was in the employ of Joseph W. Gross, M. Am. Soc. C. E., Consulting Engineer of Sacramento, as Engineer in charge of irrigation investigations, structural design, and construction. Upon the completion of this work, he was appointed Assistant Hydraulic Engineer in the California State Division of Engineering and Irrigation and assigned to reconnaissance surveys of reservoir sites. After four months he resigned to accept a position as Assistant Engineer with the City of Sacramento where he was engaged in water supply and flood-control studies and in charge of street paving. In June, 1925, he was promoted to the position of Assistant City Engineer with administrative duties. Mr. Hart served in this capacity until March, 1928, when he was made City Engineer in charge of a construction program totaling $3 000 000 annually. In November, 1928, he resigned to accept the position of Sanitary Engineer for the City of Berkeley in charge of the design and construction of a storm sewer system. This work was completed in April, 1930, and he was appointed to the position of Senior Engineer of Hydraulic Structure Design in the California State Division of Water Resources, Department of Supervision of Dams, a position he held at the time of his death.

Mr. Hart joined the military forces of the United States in August, 1917, and was commissioned First Lieutenant of Company H, 23d Engineers. The regiment went overseas on March 30, 1918, and was engaged for the greater part of the time in building and maintaining communications to the front lines. The regiment took an active part in the battles of San Mihiel and the Meuse-Argonne, returned to the United States, and was disbanded in June, 1919, Mr. Hart receiving his honorable discharge on June 17.

On August 5, 1921, he was married to Elsie A. Silman who, with their two sons, Samuel A., Jr., and William E., survives him.

Mr. Hart was an able and conscientious engineer, loyal to those with whom and under whom he was working and considerate of his subordinates. He was home loving and keenly interested in movements looking to the upbuilding of the youth of the country, and energetic in his support of constructive civic endeavors. His friendly greeting and genial smile will be sorely missed by his numerous friends and associates. He was a member of the Masonic Fraternity and of the American Legion.

Mr. Hart was elected an Associate Member of the American Society of Civil Engineers on October 10, 1916.

HERBERT McDONALD HINCKLEY, Assoc. M. Am. Soc. C. E.[1]

DIED JUNE 27, 1938

Herbert McDonald Hinckley was born in Dallas, Tex., on July 6, 1897, the son of Frank D. Hinckley, Sr., and Sarah Celeste (Chandler) Hinckley. His father was a Sheet Metal Contractor and most of his relatives were builders.

---

[1] Memoir prepared by Wyatt C. Hedrick, Esq., Fort Worth, Tex., in collaboration with Robert J. Cummins, and R. O. Jameson, Members, Am. Soc. C. E.

He received his education in the public schools of Dallas, and was graduated from the Dallas High School in 1915. He was self-taught in calculus, and from 1920 to 1924 he took an Extension Course in Structural Engineering and Reinforced Concrete from the University of Wisconsin, at Madison, Wis.

During the years of 1915 to 1920, Mr. Hinckley was associated with the Mosher Steel and Machinery Company, of Dallas, as a Draftsman and Checker. From 1920 to 1922, he served as Draftsman and Estimator for the W. C. Hedrick Construction Company, on framing plans for concrete structures and estimating quantities for buildings. From 1922 to 1924, he was again associated with the Mosher Steel and Machinery Company, of Dallas.

Mr. Hinckley was engaged as a Structural Engineer with R. O. Jameson, M. Am. Soc. C. E., Consulting Engineer, of Dallas, from 1924 to 1931. In this position he had a responsible part in the design of many large building frames handled by Mr. Jameson, among which were the Dallas National Bank (16 stories); Tower Petroleum (22 stories); Central Young Men's Christian Association (16 stories); Medical Arts Building Annex (18 stories); and many other buildings.

In 1931 and 1932 he was a Structural Engineer for Robert J. Cummins, M. Am. Soc. C. E., Consulting Engineer, of Houston, Tex. During this time he handled the design of such structures as the City County Hospital and Nurses' Home, of Houston, of which Mr. A. C. Finn was the Architect.

From 1932 to 1934 he was in private practice as Consulting Structural Engineer. During this time he was also in the employ of W. G. Clarkson and Company, Architects, of Fort Worth, Tex., as Structural Engineer. In 1934 and 1935 he was Bridge Engineer for the Forth Worth and Denver City Railway Company, of Fort Worth.

In 1935 Mr. Hinckley was the Structural Engineer for Wyatt C. Hedrick, Architect and Engineer, of Forth Worth, during which time he handled various assignments, including the Library Building of the North Texas State Teachers College, at Denton, Tex.; and, later, in 1935 and 1936, he designed the Coliseum and Memorial Tower, erected by the City of Fort Worth at a cost of approximately $733 000 as a part of its Centennial program, on which Wyatt C. Hedrick and Elmer G. Withers Architectural Company, Incorporated, were Associated Architects.

After Mr. Hinckley finished the above assignments he went to New Orleans, La., where he was employed by George P. Rice, M. Am. Soc. C. E., Consulting Engineer, on the design of various structures, during 1936 and 1937. In 1937, he went to the Virginia Bridge Company of Roanoke, Va., where he was employed as Designing Engineer until the time of his death.

He entered the Army on October 28, 1918, and was honorably discharged as a Private on January 1, 1919. He entered Artillery Central Officers Training School, at Camp Zachary Taylor, Kentucky, and was commissioned Second Lieutenant, Field Artillery Reserve, on February 1, 1919. At the time of his death, Mr. Hinckley held a commission as Major in the Field Artillery Reserve. He devised an ingenious training board for the use of students in their study of artillery problems, and took an active part in lecturing and teaching in this branch of the Service.

Mr. Hinckley was a gentleman in all his dealings with fellow engineers and was thought of always as a conscientious, hard-working engineer whose greatest delight seemed to come from the doing of a difficult task and doing it well.

In regard to Mr. Hinckley's work, Mr. Jameson states:

> "I found him to be very thorough and capable as an Engineer; his designs were economical and straightforward; and he worked constantly to improve his efficiency * * * . Mr. Hinckley was self-taught in engineering and his rise to the top as a designer is proof of his courage and determination. The Engineering Profession has lost an outstanding member in his passing."

Mr. Rice writes as follows: "Mr. Hinckley proved himself a gentleman of the first order, and I considered him one of the ablest men with whom I ever had the pleasure of working."

On September 17, 1921, Mr. Hinckley was married to Sadie Martha Burton, who survives him, together with two sons, Herbert M., Jr., and Conrad Hinckley.

Mr. Hinckley was elected an Associate Member of the American Society of Civil Engineers on November 11, 1929.

LUCIUS SANFORD HULBURD, Assoc. M. Soc. C. E.[1]

Died September 6, 1938

Lucius Sanford Hulburd was born in Brasher Falls, N. Y., on June 2, 1879. He was the son of Sanford Whittemore and Julia Amanda (Chittenden) Hulburd, and a direct descendant of William Hulburd who came from Wales, Great Britain, to New Haven, Conn., in 1630.

His preparation for entrance into the Civil Engineering College of Cornell University, at Ithaca, N. Y., included graduation from high school and three years of teaching in the public schools—he began teaching at the age of seventeen.

The summer vacations from his studies at Cornell were spent in practical engineering work, one season in the employ of the late John Bogart, M. Am. Soc. C. E., as Chainman on the construction corps supervising the hydro-electric developments by the St. Lawrence River Power Company at Massena, N. Y., and one season as Rodman in the Department of New York State Engineer and Surveyor.

During the year following his graduation from Cornell in 1903, Mr. Hulburd was employed by the S. Morgan Smith Company of York, Pa., on the construction of a 15 000-hp hydro-electric development on the Chattahoochee River near Atlanta, Ga. In June, 1904, he returned to New York State under a Civil Service appointment as Leveler in the Department of State Engineer and Surveyor. Employment by the State, with a short interruption for military service, continued until his death.

---

[1] Memoir prepared by H. O. Schermerhorn, M. Am. Soc. C. E.

The continuous State service began with four years of design and estimate work for the improved State Canal System which was then just being undertaken. His major work in this connection was computing slopes for canalized river sections of the canal system.

In March, 1908, Mr. Hulburd, as Assistant Engineer, was placed in charge of one of the first barge canal construction contracts to be awarded in the $101 000 000 canal improvement project.

In June, 1909, with a background of five years in canal design and construction, he was selected to conduct surveys and make studies for a canal to connect the Finger Lakes with the Improved Erie Canal. He was assigned the construction of the Cayuga and Seneca Canals, and for nearly seven years he was located at Seneca Falls, N. Y., first as Assistant Engineer and later as Resident Engineer.

In January, 1916, he was transferred to Residency No. 8 on the Erie Canal, and until entering military service in August, 1918, he had supervision over 38 miles of canal improvement construction through Wayne County, New York. During this interval, the military training which he received while a student at Cornell was supplemented by attendance at the Plattsburg Training Camp.

On August 25, 1918, he was commissioned Captain of Engineers and reported to Camp A. A. Humphreys, in Virginia. Orders to proceed to the port of embarkation were received on November 9, but the signing of the Armistice permitted cancellation of those orders before execution. On November 30 he was discharged, and he returned to his work in the Engineering Department of the State, supervising canal improvement construction in the vicinity of Rochester, N. Y., retracing surveys of old canal lands and investigating water supplies for State institutions.

In August, 1921, he was transferred to the main office in Albany, N. Y., to compile records of the canal improvement work. He also made inspections and reports on the construction of dams within the State.

With the canal improvement work (on which he had been employed for nineteen years under the State Engineer) brought practically to a conclusion, Mr. Hulburd became associated with the Highway Division of the State Department of Public Works and was assigned to the project for the construction of the vehicular bridge over the Hudson River at Poughkeepsie, N. Y. This work began in June, 1923, with preliminary surveys, and he continued as the principal State representative throughout construction. Foundation problems made this construction especially interesting, the two main piers being located in water 55 ft deep with an additional 60 ft and 80 ft of depth, respectively, to the rock foundation. The work was done in open caissons. Upon the opening of the bridge for traffic in August, 1930, he was appointed Superintendent of Maintenance and Operation. This supervision was extended in July, 1933, to include the Rip Van Winkle Bridge spanning the Hudson River at Catskill, N. Y., which was completed during that year. Both of these are toll bridges under a plan of operation to make them self-liquidating and eventually free.

A heart affliction from which he never recovered developed during his training at Camp Humphreys. However, he did not permit this to interfere with his activities and interest in his work. There was a sterling quality about Mr. Hulburd's character and abilities which was recognized by everybody who knew him. He possessed a fine moral fiber and so despised pretension as to appear at times modest to the extent of diffidence. Behind this reserve a vein of humor was revealed to his intimate friends to whom he was loyalty itself. As a career man in the State service, he felt a high sense of responsibility, and to this service he made no small contribution of honest and efficient accomplishment.

Mr. Hulburd never married. He attended the Presbyterian Church. He was a member of Gamma Alpha Fraternity, the Amrita Club of Poughkeepsie, the Cornell Club of Dutchess County, and Lafayette Post American Legion.

Mr. Hulburd was elected an Associate Member of the American Society of Civil Engineers on October 31, 1911.

JOHN FRANKLIN JACKSON, Assoc. M. Am. Soc. C. E.[1]

Died August 22, 1936

John Franklin Jackson was born in Scipio Township, Allen County, Indiana, on April 24, 1864. He is descended from Thomas Jackson who was a silk weaver in Mackelsfield, Cheshire County, England, as early as 1820. The silk mill of J. and F. Jackson is still in operation in that city. His grandmother was Martha Upton of Upton Hall in the vicinity of Mackelsfield. Thomas Jackson migrated to America in 1828 with his three children, Hannah, Abraham, and Adam, his wife having been killed in an accident a year previous. The family settled at Marietta, Ohio, and moved to Scipio Township, Indiana, about 1840.

John Franklin Jackson was the son of Adam Jackson and Mary Jane (Murphy) Jackson, the daughter of John Murphy, a farmer near Cincinnati, Ohio. He spent his early life on the farm, attended the country school, and was graduated from the High School at Hicksville, Ohio. He then taught school and attended the Ada Normal University, later called Ohio Northern University, at Ada, Ohio, where he was graduated from the Civil Engineering course in June, 1886.

From September, 1886, to October, 1887, Mr. Jackson served as Deputy County Surveyor of Hodgeman County, Kansas. From March, 1888, to July, 1889, he was engaged in private practice at Sioux Falls, S. Dak., where he platted several thousand lots, published a large city map, built an electric railway from Sioux Falls to East Sioux Falls, and made several preliminary surveys for the Great Northern Railway Company. In July, 1889, he was appointed City Engineer of Sioux Falls and served until April, 1890, when he resigned to engage in private work.

In September, 1890, Mr. Jackson located at Des Moines, Iowa, to travel for the Wisconsin Bridge and Iron Company of Milwaukee, Wis., with which he was associated for more than forty-five years. He started in the Erection Department and supervised the construction of bridges and other structures for the Canadian Pacific Railroad Company. In 1895 he went to Houghton, Mich., as Contracting Engineer for the Wisconsin Bridge and Iron Company and was responsible for the introduction and development of steel shaft houses for numerous mining companies in that district. He was a pioneer in this field and replaced many timber structures with steel. He also designed and constructed the first steel dam in that locality in 1901 at Redridge, Mich., which was the second steel dam ever built in the United States.

---

[1] Memoir prepared by Raleigh W. Gamble, M. Am. Soc. C. E.

While on the Upper Peninsula Mr. Jackson designed and constructed a large ore dock for the Lake Superior and Ishpeming Railway Company at Marquette, Mich., and also two large ore handling bridges for Darrow, Mann and Company. Among his more important works there were also twenty-four ore crushing plants and an equal number of large concentrating mills.

In 1906 Mr. Jackson came to Milwaukee and erected the first large plant of the A. O. Smith Corporation. He later constructed a cantilever bridge across the Mississippi River at Burlington, Iowa, and a similar structure across the Ohio River at Ironton, Ohio, as well as many other bridges in the Middle West. He also constructed wholesale coal unloading docks at Boston, Mass., and Providence, R. I., and was appointed by the Bethlehem Steel Company to inspect ore handling facilities in Chili, South America. His outstanding work was in the field of mine construction which won for him nation-wide recognition.

In 1910 Mr. Jackson was made Vice-President and Consulting Engineer for the Wisconsin Bridge and Iron Company, in which capacity he served until 1926. In 1915 he suffered a heart attack which necessitated his taking occasional rests, and in 1926, owing to failing health, he was obliged to retire; but he remained a Director of the company and served in an advisory capacity until his death.

From 1925 until 1929 Mr. Jackson acted as a Consulting Engineer with the Engineering Department of the City of Milwaukee on the construction of new bridges and the rebuilding of old ones. In 1917 and 1918 he served as a member of the Board of Examiners of engineers entering the military training camps of the United States Army. He was a member of the Western Society of Civil Engineers, the Franklin Institute, and was the first President of the Engineering Society of Milwaukee, holding that office in 1920–1921. In the fall of 1935 he was honored with a dinner by the Milwaukee Section of the American Society of Civil Engineers, of which he was then the oldest living member. He was also active in the affairs of the Rotary Club and the Milwaukee Athletic Club. His home was known to a great many "Milwaukeeans" because of its extensive gardens, stretching to the banks of the Milwaukee River and constituting his principal hobby.

Mr. Jackson was first married in 1888 to Margaret Eberl, by whom he had three children, all of whom died in infancy. On December 26, 1911, he was married to Elizabeth Tillson, a daughter of Pembrook S. and Carrie Louise (Emerson) Tillson of Manitowoc, Wis. He had one son by this marriage, John Tillson Jackson.

Mr. Jackson was elected an Associate Member of the American Society of Civil Engineers on May 2, 1894.

JOHN YOUNG JEWETT, Assoc. M. Am. Soc. C. E.[1]

DIED FEBRUARY 1, 1938

John Young Jewett was born at Gilford, N. H., on February 16, 1870. He was the son of Benjamin Quincy Jewett and Huldah Maria (Brown) Jewett, descendants of old New England families.

He received his early education in the public schools of Gilford, and from 1887 to 1890 he attended the New Hampshire College of Agriculture and Mechanical Arts (later, the University of New Hampshire), at Durham, N. H., and was graduated with the degree of Bachelor of Science. In 1892–93 and 1894–95, he attended the Thayer School of Civil Engineering, Dartmouth College, at Hanover, N. H., and was graduated with the degree of Civil Engineer.

In June, 1896, Mr. Jewett was appointed Cement Inspector of the Metropolitan Water Works of Boston, Mass., in connection with the construction of Wachusett Dam and related works at Clinton, Mass. He was engaged in experimental work on permeability of cement mortars, setting time, effect of freezing, etc. The work included both natural and Portland cements, and foreign and domestic varieties of the latter class. This was in the early days of cement when comparatively little was known of the various qualities. From January to March, 1901, he took a special course in Chemistry of Cements at the Massachusetts Institute of Technology, in Boston, Mass.

In July, 1904, Mr. Jewett became the Cement Expert of the United States Reclamation Service which was then in its formative stage. He organized and conducted the laboratory for testing of cements and related materials at Denver, Colo., and reported directly to the Director's Office, at Washington, D. C., until the opening of the Chief Engineer's Office, at Denver, in 1915. Mr. Jewett had general supervision of matters relating to purchase, test, and shipment of cement for all United States Reclamation Service projects. Auxiliary work included the examination of concrete aggregates from various projects of the Service. He made an extensive series of long-time tests on cement and aggregates, running to 10-yr periods. The study of alkali action on cement, as well as many other tests, was made under his direction.

The laboratory was taken over by the National Bureau of Standards in July, 1917, and Mr. Jewett continued doing work in his chosen field as Associate Engineer Physicist.

In October, 1918, he went to San Diego, Calif., to open a new laboratory in which work was to be done in connection with the building of concrete ships and other activities of the World War period.

He made an investigation and report for the Salt River Valley Water Users Association, in Phoenix, Ariz., in August, 1919, regarding the feasibility of cement manufacture by the Association.

---

[1] Memoir prepared by Fred D. Pyle, M. Am. Soc. C. E., and Paul Beermann, Assoc. M. Am. Soc. C. E.

The laboratory of the Bureau of Standards was taken over by the City of San Diego, in August, 1919, and Mr. Jewett became Testing Engineer for the City, in charge of all laboratory testing work.

In June, 1923, he made an examination and report on disintegration of concrete at Gem Lake Dam, in Mono County, California, and in March and April, 1928, he made an examination and report on cement and concrete problems for the Mexican National Irrigation Commission, under F. E. Weymouth, M. Am. Soc. C. E., who was Chief Engineer.

He served as a member of a Committee organized by the United States Naval Public Works Office, 11th Naval District, to investigate the condition of concrete structures exposed to action of sea water in San Diego Harbor and vicinity. His service with the City of San Diego included work on major dam construction, water development, street improvements, and building inspection. During the last eight years of his service for that city, he also directed the work in the Water Bacteriological Laboratory, in addition to his other duties.

Mr. Jewett was a member of the American Society for Testing Materials for thirty-seven years. He was a lifelong member of the Congregational Church and served for many years as an Officer of Plymouth Church, in San Diego. He also held membership in the American Concrete Institute and National Geographic Society. He was the author of several technical articles and discussions published in the *Transactions* of the Society.

Few engineers gain the reputation of dependability enjoyed by Mr. Jewett, and he could always be counted on to give his best efforts and report true unbiased results of his investigations. His ideas were always constructive and helpful to those seeking aid, and he was always willing to do any amount of work to investigate a problem thoroughly. Those who knew him will miss his kindly disposition and pleasant association. He was unusually free from animosity and enjoyed doing his part.

Mr. Jewett was married to Annie Wallace Smith, of Glasgow, Scotland, on September 3, 1896, in Malden, Mass.

On June 30, 1937, he retired from active life and moved to Paso Robles, Calif., where he passed away. He is survived by his widow and a son, J. Q. Jewett, Assoc. M. Am. Soc. C. E.

Mr. Jewett was elected an Associate Member of the American Society of Civil Engineers on September 6, 1910. In 1926, he served as President of the San Diego Section of the Society.

HENRY GORTON OPDYCKE, Assoc. M. Am. Soc. C. E.[1]

Died December 30, 1938

Henry Gorton Opdycke was born on December 23, 1870, in Philadelphia, Pa., the son of Doctor Washington Opdycke, a descendant of the original

---

[1] Memoir prepared by T. Kennard Thomson, M. Am. Soc. C. E.

Dutch Settlers in New York. His Uncle George Opdycke was Mayor of New York City from 1862 to 1864.

Henry was graduated from the High School in Jersey City, N. J. He then started work in Mechanical Engineering in the employ of, and under the instruction of, General Dudley S. Steele, pursuing the study and manufacture of iron and steel products in the Tatan Iron Works, manufacturers of railroad, dredging, and ice machinery.

When about 21 years old, Mr. Opdycke became an assistant in the employ of The Lawyers Engineering and Surveying Company, of which organization Mr. W. M. K. Olcott was Secretary, with offices at 170 Broadway, New York, N. Y.

For more than six years Mr. Opdycke was Principal Assistant to the Chief Engineer of that company, practically in charge of the office and field forces. He was frequently employed in Court as an expert witness in cases requiring unusual engineering ability. In 1895, after an examination by The Consulting Engineer of The City of New York, he was appointed a City Surveyor.

In 1897 Mr. Opdycke left The Lawyers Engineering and Surveying Company to accept a commission as Signal Officer in the United States Army, in which position he served for nearly a year, principally in Cuba, making military surveys in addition to his other duties.

In 1899 Mr. Opdycke opened his own office in New York City for the practice of engineering, surveying, etc. His work then consisted of municipal engineering, planning many systems of streets, grades, sewers, etc.

He was employed by the late Elmer Lawrence Corthell, Past-President, Am. Soc. C. E., to make maps, breakwater plans, etc., for the Cape Cod Canal. The late Alfred Noble, Past-President Am. Soc. C. E., also retained him to establish a system of co-ordinates for the Pennsylvania, New York and Long Island Railroad Terminal between 31st and 33rd Streets, Seventh and Ninth Avenues, New York City.

Warren and Wetmore, Architects, were among the enormous list of prominent concerns which availed themselves of his abilities. He planned many connections with the Rapid Transit Subways for his clients and developed large properties in New York City, such as Morris Park, for the Astor estate and others. He also had charge of the construction of the Foundations for many large buildings in New York.

Mr. Opdycke was often retained as an expert witness and as such earned a great reputation in the Courts where his natural engineering ability and careful, thorough, and exact studies and preparations for the case were of great benefit to his clients. Once, after he had won an important case for his clients, the writer was stopped on the street by a man who introduced himself as having been one of the jurymen on that case, and then told him that Mr. Opdycke and his associates were all young men of whom the jury had never heard, while the other side had a galaxy of engineers of international reputation. He said that the jury had commented on the fact that the young men, in that case, knew every detail of their work, while the older men, of great reputations, only seemed to know what the contractors had told them about the subject.

Mr. Opdycke for many years was probably the leading specialist on the vibration of buildings, and other structures, due to the subway construction, etc., having designed and constructed machines for recording such vibrations in the Grand Central Station (due to trains) and in other buildings.

One of his machines recorded movements, or vibrations, of as much as one-eighth of an inch—both vertically and horizontally—in a building every time a big engine started or stopped running in another building more than 700 ft away from the recording machine.

During the construction of the Seventh Avenue Subway, Mr. Opdycke directed the underpinning of the Metropolitan Opera House, the New York Produce Exchange, and other difficult underpinning jobs.

In 1925, as Consulting Engineer of the Eighth Avenue Association, later the West Side Chamber of Commerce, he developed his plan of submerged by-passing of gas mains during subway construction. Previously gas mains had been carried on over-head structures during subway construction, which resulted in losses to merchants, annoyance to pedestrians, and fire hazards.

Mr. Opdycke served as Managing Director of the Broadway Association and was instrumental in forming the Sixth Avenue Association with which he was connected for many years. It is of interest that later his son, Barkley, was also connected with the development of Sixth Avenue, being in charge of work for one of the contractors on the subway. Among the Major's many clients were R. H. Macy and Co., John Wanamaker, The Chemical National Bank, Hotel Imperial, Hotel Ansonia, 1270 Broadway, etc.

He organized the Signal Corps of the National Guard of New Jersey, and, during the Spanish-American War, served as Signal Officer of the Department of Mananzas and Santa Clara, Cuba.

Major Edward Van Winkle writes:

> "He grew up in Jersey City with me, married a sister of a classmate of mine. He organized the first Signal Corps in New Jersey National Guard in the nineties and commanded the battalion for the first years. He was a very nice fellow, thorough in his work and had a natural bent for history."

During the World War, Major Opdycke spent 14 months in France as Chief Signal Officer of the Intermediate Section of the American Expeditionary Forces. For this service he was made a Chevalier of the Legion of Honor (a distinguished American Colonel once stated that he would cheerfully have given 10 years of his life if he could have earned that honor). Major Opdycke was also cited by the United States Government.

In 1921 and 1922 he managed the Veterans Bureau of the Second District, which embraced New York, Connecticut, and New Jersey, a clearing house for Federal agencies helping Ex-Service men.

Major Henry G. Opdycke was a born engineer with unusual ability and foresight, and industry. He was tireless in looking after the interests of his clients and friends. He was an authority on acoustics.

He had an intense pride in, and affection for, his family, loyalty for his friends, and " carried on " to the last in spite of the increasing infirmities due to his work in the World War.

Surviving are his widow, the former Ida Louise Stryker, a descendant of General Stryker; a son Barkley Opdycke, Civil Engineer and Surveyor; and three grandchildren, Elizabeth Louise Opdycke, James Barkley Opdycke, Jr., and Jan Opdycke.

He was a member of many Military Organizations. For thirty years before his death he had all the qualifications for full membership in the Society and was often urged to transfer to that grade. It is a profound tribute to his innate modesty that he was content with the grade of Associate Member.

Major Opdycke was elected an Associate Member of the American Society of Civil Engineers on September 7, 1904.

OTTO COFFEEN FITZ RANDOLPH, Assoc. M. Am. Soc. C. E.[1]

Died May 8, 1938

Otto Coffeen Fitz Randolph was born in Arkansas City, Kans., on November 27, 1890, the son of Jackson Fitz and Lacie (Coffeen) Randolph. He received his primary and High School education in the public schools of Chicago, Ill., and his university education at the University of Illinois, at Urbana, Ill., where he enrolled in 1908. After a year's absence to earn school money, he was graduated from that University with the Class of 1913, with the degree of Bachelor of Science in Civil Engineering.

During his year of absence from college and during vacation periods, Mr. Randolph worked as Timekeeper and Laborer for George Hinchliff Company; as Draftsman for the Robbins Conveying Belt Company; and as Masonry Inspector for the Illinois Central Railroad Company. After his graduation, he entered the employ of the Michigan Central Railroad Company as Bridge Inspector and Investigator of stresses in bridges east of Jackson, Mich. Later, he was made Inspector in charge of the bridge being built over the Lake Shore Yards, in Detroit, Mich.

From July, to December, 1915, Mr. Randolph was Engineer in charge of building and structural appraisal of the Detroit properties of the Michigan State Telephone Company. From December, 1915, to September, 1916, he was Construction Engineer for the Timpkin Detroit Axle Company in charge of the construction of two 4-story factory buildings and of the design of all factory additions. From September, 1916, to June, 1917, he was Superintendent of The Austin Company in charge of the construction of the plant for the Michigan Steel Tube Products Company, the design of a power house for the same Company at Detroit, and the construction of buildings for the Dow Chemical Company, of Midland, Mich.

---

[1] Memoir prepared by W. L. Abbott, Esq., Chicago, Ill., assisted by Edward Haupt, M. Am. Soc. C. E.

On June 6, 1917, Mr. Randolph joined the 16th Railway Engineers, U. S. Army, in Detroit, and on July 28, with the rank of Second Lieutenant, he sailed with his regiment for France. There he was engaged in the construction of main advance post warehouses at Is-sur-Tille, the construction of narrow and standard-gage railroads on the British front north of Arras, and of a 40 000-bed hospital at Mesves sur Bulcy. In addition to this work, the 16th Combat Engineers, in March, 1918, took its place at the front, with the British on the Aisne River where the great German drive was halted and turned back.

Because of exceptional ability shown in expediting construction work, Mr. Randolph was advanced in rank to First Lieutenant and then to Captain, and on September 19, 1918, he was sent back to the United States, stationed at Camp Humphreys, Virginia, promoted to the rank of Major, and ordered to form a regiment of sappers of which regiment he was to be the Colonel.

With the declaration of the Armistice, all organizing work was stopped, and soon, thereafter, Major Randolph resigned his commission and entered the employ of the H. K. Ferguson Company, General Contractors, as District Superintendent in charge of the Chicago office. As such, he was engaged on the construction of a furniture plant for Showers Brothers, of Bloomington, Ind.; a power plant and factory for Nordyke and Marmon, at Indianapolis, Ind.; and the design and construction of a straw-board paper mill for The Hinde and Dauch Paper Company, at Fort Madison, Iowa.

After two years with the Ferguson Company, Mr. Randolph resigned, and, in 1922, with some of his Army associates, organized the Engineering and Contracting Company—Otto Randolph, Inc.—of which he was President and Treasurer. The Company was engaged in a variety of construction work—residences, hotels, factories, sub-stations, power plants, roads, and bridges, in which work it prospered all through the depression of 1929–1935.

Not only was the Company prosperous in the contracting business but Mr. Randolph, personally, was prominent in contractors' organizations, having served as President of the Landis Award Association and President of the Mason Contractors' Association for negotiations with union labor. Although somewhat brusk in outward manner, he was of a genial nature and of the type known as a " square shooter "—one whose ethics and business integrity never wavered for a temporary advantage, however great, in his dealings with competitors, clients, or labor officials.

Mr. Randolph was a man of unusual energy and physical strength, which were contributing causes to his death, at the age of forty-seven, resulting from a too strenuous participation, one evening, in the events of a fathers' and sons' athletic competition. At two o'clock the next morning, he had a paralytic stroke that rendered him helpless. He was taken to a hospital and was making slow progress toward recovery, when pneumonia set in, causing his death a few days later. He was buried, May 11, 1938, in Rosehill Cemetery, Chicago, with impressive military honors under the direction of Castle Post No. 151 of the American Legion of Illinois.

Mr. Randolph was a member and Past-President of the Illini Club of Chicago, a member of the Union League Club, of Chicago, the University

Club, of Chicago and the Chicago Engineers' Club, of which he was Past-President. He was also a member of the Evanston (Ill.) Golf Club. He was a registered Structural Engineer in several States, and a member of the American Society of Military Engineers, the American Legion, Phi Gamma Delta Fraternity, the Masonic Order, the Democratic party, and the Presbyterian Church.

On June 16, 1917, ten days after he had enrolled in the Army, Mr. Randolph was married to Helen Abbott, a college classmate. This happy union lasted fourteen years, when Mrs. Randolph died November 3, 1932, leaving four children, William, Otto, Josephine, and Burleigh. On February 20, 1935, Mr. Randolph was married to Wilma Hall, who bore him a son, Michael.

Mr. Randolph was elected an Associate Member of the American Society of Civil Engineers on September 9, 1919.

WILLIAM SHEARER, Assoc. M. Am. Soc. C. E.[1]

DIED NOVEMBER 23, 1938

William Shearer was born at Burson, Calaveras County, California, on October 20, 1886, the son of Willow Spring and Bertha E. (Gaylord) Shearer. His preliminary education was received in the Public Schools of Marysville, Calif., and he was graduated from the High School in that city in June, 1908.

Shortly after leaving High School he accepted a job with the Pacific Gas and Electric Company in Marysville as a sub-station operator. In January, 1910, he accepted a position with Leslie B. Crooks, private civil engineer and land surveyor, engaged in business in Yuba and Sutter Counties, California, this being his first contact with the civil engineering field. His association with Mr. Crooks lasted until August, 1915, interrupted only by a 2-yr assignment with the Pacific Gas and Electric Company where he served as Construction Foreman on power-line, sub-station, and power-house construction. While with Mr. Crooks, he was engaged on irrigation and drainage projects, highway and bridge construction, and general land surveying.

Realizing that advancement in the profession demanded further educational qualifications, Mr. Shearer entered the College of Engineering at the University of Nevada, at Reno, Nev., in August, 1915. His undergraduate work, however, was interrupted in October, 1917, when he enlisted in the United States Navy. His war service with the Navy lasted until June, 1919, and during his enlistment he was assigned to ships in both home and foreign waters, serving as an Electrician and Ensign Engineer Officer.

After his discharge from the Navy, he served a short assignment with the Nevada State Highway Department as Resident Engineer on highway construction, and re-entered the University of Nevada in January, 1920. He completed his course in May, 1920, receiving a Bachelor of Science in Civil Engineering. At the University he distinguished himself in scholarship and extra-curricular activities. He was affiliated with Sigma Alpha Epsilon Fraternity, was elected to Phi Kappa Phi (Honorary) Fraternity, and was a member of Coffin and Keys, a local honorary society.

---

[1] Memoir prepared by Committee of the Sacramento Section, consisting of Owen G. Stanley, Chairman, M. Am. Soc. C. E., Henderson E. McGee, Assoc. M. Am. Soc. C. E., and O. Haven Hart, Jun. Am. Soc. C. E.

From July, 1920, until April, 1921, he was again employed by the Pacific Gas and Electric Company, in the vicinity of Marysville, as Foreman on the construction of transformer stations, hydro-electric plants, and power lines. During 1921 he served a short assignment with the U. S. Engineer Office, Sacramento District, as Chief of Survey Party on hydrographic and topographic surveys along the Sacramento River.

In April, 1922, Mr. Shearer was made Assistant City Engineer of the City of Marysville, and served in that capacity until January, 1923, when he was elected County Surveyor of Sutter County, California. He served in this capacity until April, 1934, and was responsible for the construction of many highway and other county improvements. During his tenure of office all bridges and highways were constructed on designs made by Mr. Shearer, and built under his supervision. The above contacts led Mr. Shearer to an interest in the fields of City Planning and Management as applied to smaller units, in which he became quite active.

In April, 1934, he returned to the U. S. Engineer Office, Sacramento, and remained on this assignment until the accident which caused his untimely death in November, 1938. He was engaged on various projects connected with flood control, river and harbor improvements, and the control of hydraulic mining débris.

Mr. Shearer was a registered Civil Engineer and Land Surveyor in the State of California. He was a member of the Masonic Order, Knights Templar, Scottish Rite, and Mystic Shrine, and also a member of the Order of the Eastern Star. He was a conscientious and efficient engineer of unquestioned integrity, a loyal friend, and a worthy citizen.

On September 8, 1928, he was married to Eva Kennedy, who, with two children, William Kennedy and Margaret Sue, survives him.

Mr. Shearer was elected an Associate Member of the American Society of Civil Engineers on July 11, 1921.

JOSEPH WARREN SILLIMAN, Assoc. M. Am. Soc. C. E.[1]

Died September 22, 1938

Joseph Warren Silliman was born in Ashtabula, Ohio, on August 25, 1865, and was graduated from Allegheny College, at Meadville, Pa., in June, 1889, with the Degree of Civil Engineer.

Immediately after his graduation, Mr. Silliman obtained a position as Rodman with the firm of Cole, Alvord, and Shields, Engineers, of Chicago,

---

[1] Memoir prepared by Benjamin Franklin, M. Am. Soc. C. E.

Ill. He resigned from this firm in February, 1890, to accept a position as Instructor at his Alma Mater, Allegheny College.

Evidently teaching, as a profession, did not appeal to him, for he resigned at the end of the college year to become an Assistant in the firm (well known at that time) of Patton and Frank, Civil Engineers of Duluth, Minn., remaining with them for more than five years.

On severing his connection with Messrs. Patton and Frank in October, 1895, he went to Philadelphia, Pa., where he spent the remainder of his professional life, with the exception of one year spent in Long Island as Chief Engineer of the New York and Queen's County Railway Company, and another year as Superintendent of Construction for the Wheeling and Western Railway Company of Bridgeport, Ohio.

Among the important positions held by Mr. Silliman while in Philadelphia was his connection with the Peoples and Union Traction Companies in charge of construction and maintenance of power station and track. Later he became Assistant Engineer for the Philadelphia Rapid Transit Company in charge of maintenance of way, covering construction of underground conduits, track, and roadway.

At the conclusion of this work, he entered the employ of the Highway Department of the City of Philadelphia, passing through various grades as Bridge Inspector; in charge of sewer construction; and finally reaching the position of District Engineer in charge of Highway Construction and Maintenance.

Mr. Silliman was noted for his thorough technical knowledge—which was ripened by a valuable and varied experience—and for reaching his objectives through a very genial and pleasant personality.

He had many warm and constant friends in Philadelphia who respected his high ideals, his sincerity, and his genuine kindliness. Mr. Silliman never married.

His membership in the following organizations indicated his deep interest in his profession: Member of the Engineers' Club of Philadelphia since 1896—a period of 43 years; Member of the Forestry Association of Pennsylvania. He was also active in the Philadelphia Section of the American Society of Civil Engineers.

Mr. Silliman was elected an Associate Member of the American Society of Civil Engineers on September 2, 1914.

HARVEY ALFORD TUTEWILER, Assoc. M. Am. Soc. C. E.[1]

DIED DECEMBER 8, 1938

Harvey Alford Tutewiler was born in Indianapolis, Ind., on June 9, 1890, the son of Charles W. and Caroline (Alford) Tutewiler. He was graduated from High School in June, 1906, and shortly afterward entered the Engineering Department of the City of Indianapolis. From June, 1906, until October, 1919, he was continuously employed in this department, with the exception of nine months of service in the United States Army during the World War.

---

[1] Memoir prepared by E. B. Rayburn, Jr., Assoc. M. Am. Soc. C. E.

He served his apprenticeship in the Engineering Department of the City of Indianapolis from 1906 to 1910, and acquired an engineering foundation in the various capacities of Rodman, Levelman, Inspector, and Instrumentman. In 1910 he entered the Engineer's Office as Draftsman and Estimator. His new duties introduced him to the fundamentals of street and bridge design and layout. Quite a clamor also had arisen for grade-crossing eliminations in the southern part of the city and it was necessary to prepare many preliminary plans and estimates for the purpose. July, 1912, saw him further advanced to the position of Chief Draftsman and Office Engineer. About this time the tempo of street building quickened appreciably as the demand for hard-surfaced streets increased with the mounting number of motor cars in use. Construction technology was also advancing rapidly, and the young engineer without a formal engineering education had to keep continually on his toes in his successful effort to remain abreast of this advance.

His ability to get his job done was rewarded in 1915 by advancement to the position of Assistant City Engineer. As such he was directly responsible for the planning, construction, and maintenance of the city's continually growing street system. During this period the number of miles of new hard-surfaced streets showed a tremendous increase, which was in keeping with the general trend throughout the country. It was necessary to expand the Department's Engineering and Inspection divisions to handle this increased volume adequately, and part of the system he set up to supervise and expedite construction still remains in use to-day.

The World War interrupted his engineering career for nine months beginning in October, 1918. He was unable to escape from construction, however, as he enlisted in the Army's Construction Division at Fort Knox, Kentucky, and as a First Lieutenant he continued his rôle of road and street builder.

On his return from the Army he resumed his post in the Engineering Department, but his Army experience had left him with a restlessness which the duties of his job could not overcome. Accordingly, in October, 1919, he joined The Mansfield Engineering Company as Superintendent and General Manager. The company was engaged in heavy engineering and building construction and one of his first assignments was the supervision of the construction of a hydro-electric plant at Monticello, Ind. He could not, however, forsake his old love—street building—and upon completion of the job at Monticello the company forsook heavy construction to specialize in the building of concrete and asphalt streets. Under his direction the paving business increased yearly and even to-day the product of those early years bears evidence of the quality of his workmanship.

The company also branched out into the manufacture of a dragline bucket, but the death of the head of the firm in 1925 brought about the dissolution of The Mansfield Engineering Company, and in its stead was formed the Standard Paving Company, with Mr. Tutewiler as part-owner and President. The activities of the company followed closely those of its predecessor, but much of the volume and allure had vanished from street building by the end of the 20's and he was again on the lookout for a business which would absorb more of his boundless energy.

The search ended in 1931 with the founding of the Ready Mixed Concrete Corporation. As Principal Owner and his own General Manager, Mr. Tutewiler had ample opportunity to exercise his talents in the promotion of the use of his product—pre-mixed concrete. In a city where concrete had previously been mixed on the site of the work, pre-mixed concrete was still regarded as somewhat of a novelty, although its use had already become general in most large population centers. For several years, therefore, he had his hands full in the building up and expansion of a market which would absorb the facilities of his plant. Until his death in an automobile accident he had seen each year's volume exceed that of the preceding year, and the growth of his plant and equipment had increased accordingly.

Aside from his business interests, he loved hunting and fishing and would never overlook an opportunity to engage in either of them. He was active in the social and fraternal life of his city and belonged to numerous organizations of this nature. During the year preceding his death he had been able to devote some of his time to affairs of a strictly civic nature, and undoubtedly he would have occupied himself more and more with things of this sort as his business became more routine, and demanded less of the constant attention he had found necessary heretofore.

He was a licensed Professional Engineer, a member of the Indiana Section of the American Society of Civil Engineers, and of the Indiana Engineering Council.

In 1910 he was married to Ora Harcourt. His widow, their one child, Martha Tutewiler Simpson, and a sister, Mrs. Fred L. Evans, survive him.

Mr. Tutewiler was elected an Associate Member of the American Society of Civil Engineers on October 29, 1934.

WILLIAM NOEL ALLISON, Jun. Am. Soc. C. E.[1]

DIED JULY 29, 1938

William Noel Allison was born in Golden, Colo., on January 1, 1909, the second child of William F. and Mabel (Hegeman) Allison. He attended Grammar School, High School, and College in Seattle, Wash., where his father was Professor of Municipal and Highway Engineering at the University of Washington. Mr. Allison received his technical training at the University of Washington from which he was graduated in December, 1931, with the degree of Bachelor of Science in Civil Engineering. He continued his training during the following year and received the additional degree of Master of Science in Civil Engineering, also from the University of Washington, in June, 1932. His was an enviable college record; he was an excellent student, and he combined admirably his technical training and balanced social and student activities to endear his friendship to both his classmates and the Faculty. He was a member of Alpha Kappa Lambda Fraternity.

---

[1] Memoir prepared by L. Vaughn Downs, Jun. Am. Soc. C. E.

During the year, 1927–1928, Mr. Allison was engaged as a Draftsman for the Wallace Bridge and Structural Steel Company, in Seattle. Later, during summer vacations from College, he was employed on surveying assignments by the State of Washington, and by C. W. Harris, M. Am. Soc. C. E., of Seattle. After the completion of his college training he was employed by the Boeing Airplane Company, and the United States Coast and Geodetic Survey (both of Seattle), and the Pacific Car and Foundry Company, of Renton, Wash. In May, 1934, he again entered the service of the United States Government, and was employed by the Bureau of Reclamation on the construction of the Grand Coulee Dam. He continued with this organization as an Inspector and as a Junior Engineer, until his untimely death.

Mr. Allison was married on July 16, 1938, to Margaret Prosser, of Veradale, Wash. He died in Amarillo, Tex., on July 29, 1938, after a short illness while en route to the City of Mexico, Mexico, on his honeymoon. He is survived by his widow, his mother, and two sisters.

His passing cut short a career of much promise for he was diligent in his efforts, strong in character, and keen in intellect. He was possessed of a good sense of humor, a kindly regard for his fellow men, and an intense interest in social and economic problems.

Mr. Allison was elected a Junior of the American Society of Civil Engineers on May 23, 1932.

ROBERT EDWARD AUSTIN, Jun. Am. Soc. C. E.[1]

Died November 17, 1937

Robert Edward Austin was born on January 2, 1914, the son of Seneca B. Austin and Elizabeth M. Austin, at Jacksonville, Fla.

He was graduated from the University of Florida at Gainesville, Fla., and was awarded the prize from the Florida Section of the American Society of Civil Engineers for his outstanding work as a student.

Mr. Austin was an exceptionally able young engineer. At the time of his death he was employed by The Weber Company, Inc., of Jacksonville, as Supervising Engineer for the construction of a tall reinforced concrete chimney for the new pulp and paper mill of the National Container Corporation. Previous to this he was employed by the Shore-line Builders, Inc.

---

[1] Memoir prepared by Carl Weber, Esq., Jacksonville, Fla.

of Jacksonville, as Field Engineer in the construction of the water-supply intake tunnels of the municipal electric plant.

He died of pneumonia, after a short illness, on November 17, 1937, in Jacksonville, at the age of 23 years. He is survived by his parents, one brother, Seneca B. Austin, Jr., and two sisters, Mrs. A. V. McDowell and Ruth Austin.

Although Mr. Austin was a young man and consequently his record of accomplishments a brief one, he was nevertheless one of the outstanding young men in the engineering profession. He took his work seriously and proved that he possessed engineering skill and knowledge far beyond that which could be expected from a man of his age.

He was a member of the Florida Engineering Society and the Jacksonville Professional Engineers Club.

Mr. Austin was elected a Junior of the American Society of Civil Engineers on November 9, 1936.

ARTHUR SAMUEL BENT, Affiliate, Am. Soc. C. E.[1]

DIED FEBRUARY 17, 1939

Arthur Samuel Bent was born in Downieville, Calif., on April 25, 1863, the son of Henry Kirke White Bent and Jessie (Crawford) Bent, who were of staunch New England heritage. Arthur went to Los Angeles, Calif., in his early boyhood, and was educated in the Los Angeles Public Schools.

In his young manhood he came to believe that great development lay ahead for Southern California and that the distribution and development of water would be conspicuous in that growth. Accordingly, he became interested in the manufacture and installation of concrete pipe, and was one of the few pioneers in this industry, starting in 1883 with crude hand methods and little knowledge of concrete. For many years he was an authority on this class of work throughout the United States. As far back as 1891 he constructed the main supply water-line for the Temescal Water Company of Riverside County, California. In later years he took personal charge of a large gravity line near Boulder, Colo., for the Central Colorado Power Company, and a large water-supply line for the City of Pendleton, Ore.

Seeking the improvement of conditions of which he was a part characterized Mr. Bent's entire life, and he did much, over a period of thirty years, to improve the quality, methods of manufacture, and specifications of concrete pipe. He laid many miles of this pipe throughout Southern California. After his brother, H. Stanley Bent, became associated with his construction activities, the interest of their firm gradually extended into larger engineering construction works, ultimately under the name of Bent Bros., Inc.

Mr. Bent was President of Bent Bros., Inc., engineering contractors. This firm constructed numerous dams, irrigation systems, and other large projects throughout Western America. For many years, based on integrity, industry, and accomplishment, it has enjoyed a place of unique confidence in various phases of engineering construction—engineers, financiers, and material suppliers. Between the years of 1920 and 1925, the firm constructed for the large oil companies in California about forty oil-storage reservoirs, having a capacity of from 500 000 barrels to 3 000 000 barrels each.

---

[1] Memoir prepared by J. B. Lippincott, Hon. M. Am. Soc. C. E.

From the years 1920 to 1939 the firm also constructed eighteen dams of various types, all of which were concrete except one—the Henshaw Dam in San Diego County, California, which was an earth-fill structure. The better known of these dams were: Bull Run for the City of Portland, Ore., for water supply; Exchequer Dam built for the Merced Irrigation District for irrigation purposes; Pacoima Dam built for the Los Angeles County Flood Control; Morris Dam built for the City of Pasadena, Calif., for the city water supply; and Conchas Dam, New Mexico, built under the Army Corps of Engineers for flood control.

Mr. Bent's most notable characteristic was his great versatility and his interest in many types of public-welfare enterprises. He contributed greatly to the public life of the community in which he lived. One of his outstanding ambitions was to elevate and establish the general standing of the contractor in the community and in the construction industry, throughout the United States. His life was an outstanding example of the practice of high ethics in contracting. The company of which he was president so lived up to these standards that contracts were often awarded to it on slight formality.

The ideals and labor of Arthur Bent had a profound effect on the organization of the Associated General Contractors of America, of which he became national president in 1924, following his activity in the organization and presidency of the Southern California Chapter. These ideals were expressed in an address that he made before that organization in 1922, in which he stated:

> "In a little while other men will take the places of us all. It is an inspiring thought to me that we are not only blazing the way for them and straightening the path for their feet, but we are establishing practices and ideals and standards that will draw better and better men into the contracting game and all down through the years will inspire them with a zeal for worthy service; and that, I think, is the finest definition of Americanism that I know."

It is stated in the contractors' magazine, *The Contractor,* that "It is to the ideals of Arthur Bent and his co-workers in the early days of the A.G.C. that the association owes the sound position and high esteem it holds today."

During his active construction years, he was never too busy to be human. Many of his employees have remembered for years his kindly word, courtesy, and real interest in them.

The following positions which he has held are illustrative of Mr. Bent's versatility:

He was City Editor of the Los Angeles Evening Express at the age of eighteen. In 1926 he was President of the Los Angeles Chamber of Commerce. On the occasion of his inauguration to this office, he delivered an address entitled "Lorenzo the Magnificent," in which he held up ideals to the City of Los Angeles similar to those which prevailed in Florence, Italy, under

Lorenzo. Elected as the head of a large commercial organization, he had the courage, on taking office, to stress the value of culture in a community and the fact that mere size could not make a city great. His address is still remembered in Los Angeles for its high ideals and eloquence. He was a Director of the U. S. Chamber of Commerce from 1923 to 1929, and a Director of the California State Chamber of Commerce from 1926 until his death.

As a further illustration of the varied culture of the man, he was on the advisory board of the Los Angeles Philharmonic Orchestra, and served a term as a member of the Los Angeles Board of Education. He held the position of Trustee of Pomona College, Claremont, Calif., continuously from 1921 until his death. Both as a member of the Board of Education of Los Angeles and as a Trustee of Pomona College, Mr. Bent followed in the footsteps of his father. In 1927 he was presented with a watch by the Los Angeles Realty Board as the City's most useful citizen during 1926. As a great patriot, he was President of the distinguished Lincoln Club of Los Angeles in 1938, and was re-elected for 1939.

Abounding in ready wit and a sense of humor, Mr. Bent also had a charming personality and was greatly beloved by his associates. The following excerpts from quotations made at the time illustrate the genuineness of this sentiment:

> "He was one of the rarest and most charming men I have ever known. Los Angeles will never be the same without him. There is a lonesome place against the sky."

* * *

> "He was not only an inspiration to all who knew him intimately but he always had the highest esteem and respect of those who knew him slightly."

* * *

> "He gave much to the world in friendship in kindness by example, in good deeds, in upholding the right always. I shall think of him for the light he gave others. And never did I hear him say an unkind much less an unjust word."

* * *

> "He is not only remembered by men of his station and ideas, but by the humble man in the street also."

* * *

> "Few are gifted with the sympathetic understanding of humanity that was his—few endowed with the tolerance and the kindly but just appraisal of men and their efforts."

* * *

> "His splendid character, his uprightness, his love for truth and sincerity together with his personal charm will be an inspiration to all who knew and loved him. He has left in memory a streak of gold in the lives of all his friends who remain."

* * *

> "To me his most outstanding characteristics were his love of humanity and an earnest and unfailing desire to be of service to his fellow man. He had a rare capacity for friendship."

Mr. Bent was elected an Affiliate of the American Society of Civil Engineers on November 28, 1916.

PIPE LINES.

" Economic Pipe Sizes for Water Distribution Systems." Thomas R. Camp. 190. Discussion: Clinton L. Bogert and J. M. M. Greig, Charles M. Mower, Jr., A. C. Michael, Ellwood H. Aldrich, M. H. Klegerman, and F. Knapp. 203.

" Transportation of Sand and Gravel in a Four-Inch Pipe." G. W. Howard. 1334. Discussion: Fred R. Brown, Josef E. Montgomery, Elliott J. Dent, David L. Neuman, Morrough P. O'Brien and R. G. Folsom, R. L. Vaughn, M. P. Durepaire, Pierre F. Danel, and H. S. Gladfelter. 1349.

PLASTIC MATERIALS.

Effect of plasticity index on resistance to earth failure. 1423.

PLATES, STEEL.

See **STEEL PLATES.**

POWER COST.

" Cost of Energy Generation ": Second Symposium on Power Costs. John C. Page, C. F. Hirshfeld and R. M. Van Duzer, Jr., H. K. Barrows, Ezra B. Whitman, Maurice R. Scharff, and W. F. Uhl. 1050. Discussion: Joel D. Justin, Frank H. Mason, W. V. Burnell, Daniel W. Mead, A. G. Christie, William E. Rudolph, Louis Elliott, H. G. Gerdes, Leverett S. Lyon, John T. Madden, R. L. Thomas, Theodore B. Parker, Philip Sporn, L. N. McClellan, James C. Bonbright, R. Robinson Rowe, V. B. Libbey, Edwin D. Dreyfus, R. H. Parsons, and F. Knapp. 1149.

" Economic Aspects of Energy Generation ": A Symposium. Geo. A. Orrok, Frank H. Rogers, Joel D. Justin, Philip Sporn, Ralph E. Freeman, and B. A. Thresher. 942. Discussion: W. S. Finlay, Jr., R. M. Riegel, Ralph Bennett, J. M. Mousson, Ben C. Sprague, V. M. Marquis, R. L. Sackett, D. J. McCormack, I. E. Moultrop, M. M. Samuels, E. W. Kramer, Paul E. Gisiger, F. A. Dale, Ray S. Quick, F. Knapp, and D. S. Jacobus. 1009.

POWER INDUSTRY.

Cost of power, showing growth of power industry in the United States. 1147.

Electric power in economic perspective. 1001.

Social implication of technological trends in the power industry. 995.

POWER-PLANTS.

" Cost of Energy Generation ": Second Symposium on Power Costs. John C. Page, C. F. Hirshfeld and R. M. Van Duzer, Jr., H. K. Barrows, Ezra B. Whitman, Maurice R. Scharff, and W. F. Uhl. (With Discussion.) 1050.

" Economic Aspects of Energy Generation ": A. Symposium. Geo. A. Orrok, Frank H. Rogers, Joel D. Justin, Philip Sporn, Ralph E. Freeman, and B. A. Thresher. (With Discussion.) 942.

" Energy Mass Diagrams for Power Studies." John W. Hackney. (With Discussion.) 1644.

POWER TRANSMISSION.

Elements of cost of energy generation. 1051.

PUBLIC WORKS.

"Engineering Economics and Public Works": A Symposium. Frederic H. Fay, Daniel W. Mead, Henry Earle Riggs, and William J. Wilgus. 635. Discussion: J. K. Finch, Elliott J. Dent, C. Frank Allen, Bradley G. Seitz, Alfred Allen Stuart, Pierce P. Furber, R. F. Bessey, Donald M. Baker, Philip W. Henry, H. K. Barrows, Harry A. Wiersema, J. D. Galloway, E. S. Martin, K. Bert Hirashima, Louis E. Ayres, John H. Meursinge, and Samuel B. Folk. 701.

RAINFALL.

"Flood Routing." Edward J. Rutter, Quintin B. Graves, and Franklin F. Snyder. (With Discussion.) 275.

"Relation of Rainfall and Run-Off to Cost of Sewers." John A. Rousculp. 1473.

REPORTS OF COMMITTEES.

"Interstate Water Problems." Final Report of the Committee of the Irrigation Division on Interstate Water Rights. H. K. Barrows, C. J. Bartholet, C. S. Clark, Edward Hyatt, George S. Knapp, G. E. P. Smith, J. C. Stevens, R. J. Tipton, Abel Wolman, and M. C. Hinderlider. 1822.

RESERVOIRS.

"Flood Routing." Edward J. Rutter, Quintin B. Graves, and Franklin F. Snyder. (With Discussion.) 275.

Low-flow regulation by Pymatuning Reservoir. 832.

RIVERS.

"A Theory of Silt Transportation." W. M. Griffith. (With Discussion.) 1733.

"Energy Mass Diagrams for Power Studies." John W. Hackney. (With Discussion.) 1644.

"Flood Routing." Edward J. Rutter, Quintin B. Graves, and Franklin F. Snyder. (With Discussion.) 275.

Improvements for navigation on the Missouri River. 672.

"Observed Effects of Geometric Distortion in Hydraulic Models." Kenneth D. Nichols. (With Discussion.) 1488.

"Stream Pollution in the Ohio River Basin": A Symposium. George E. Barnes, Harold W. Streeter, Charles E. Ryder, W. L. Stevenson, E. S. Tisdale, D. E. Davis, J. E. Root, and Abel Wolman. (With Discussion.) 812.

The Columbia Basin project. 676.

See also **WATER, FLOW OF, IN OPEN CHANNELS.**

RUN-OFF.

"Flood Routing." Edward J. Rutter, Quintin B. Graves, and Franklin F. Snyder. (With Discussion.) 275.

"Relation of Rainfall and Run-Off to Cost of Sewers." John A. Rousculp. 1473.

SAFETY DEVICES AND MEASURES.

"Increasing the Traffic Capacity and Safety of Thoroughfares": A Symposium. Lewis W. McIntyre, Donald M. McNeil, Arnold H. Vey, and E. L. Schmidt. (With Discussion.) 440.

"Motor Transportation—A Forward View": A Symposium. C. F. Kettering, Thomas H. MacDonald, and Leroy C. Smith. (With Discussion.) 1562.

SAND.

"Transportation of Sand and Gravel in a Four-Inch Pipe." G. W. Howard. (With Discussion.) 1334.

SANITATION.

Sanitation problems incidental to floods. 844.

SEPTIC TANKS.

"Multiple-Stage Sewage Sludge Digestion." A. M. Rawn, A. Perry Banta, and Richard Pomeroy. (With Discussion.) 93.

SEWAGE DISPOSAL.

"Deoxygenation and Reoxygenation." C. J. Velz. 560. Discussion: Earle B. Phelps. 573.

"Economics of Sewage Treatment." George J. Schroepfer. 1210. Discussion: Charles Gilman Hyde, and Frederic Bass. 1239.

"Grit Chamber Model Tests for Detroit, Michigan, Sewage Treatment Project." George E. Hubbell. (With Discussion.) 214.

"Multiple-Stage Sewage Sludge Digestion." A. M. Rawn, A. Perry Banta, and Richard Pomeroy. 93. Discussion: Edward W. Moore, Willem Rudolfs and H. Heukelekian, Hermann Bach, and C. E. Keefer. 120.

SEWERAGE.

"Relation of Rainfall and Run-Off to Cost of Sewers." John A. Rousculp. 1473.

SHEET PILING.

See **PILES.**

SILT.

"A Theory of Silt Transportation." W. M. Griffith. 1733. Discussion: Joe W. Johnson, G. W. Howard, Harry F. Blaney, E. W. Lane, O. A. Faris, J. E. Christiansen, Samuel Shulits, Gerald Lacey, Glenn W. Holmes, Hunter Rouse, S. G. Bauer, and C. C. Inglis. 1749.

SLABS.

"The Design of Rock-Fill Dams." J. D. Galloway. (With Discussion.) 1.

SOILS.

Characteristics of soil types. 1413.

"Graphical Representation of the Mechanical Analyses of Soils." Frank B. Campbell. 150. Discussion: Donald M. Burmister, A. J. Weinig, Carl H. Kadie, Jr., Carlton S. Proctor, T. T. Knappen, Jacob Feld, Howard F. Peckworth, Joel D. Justin, L. B. Olmstead, T. A. Middlebrooks, Frank E. Fahlquist and Waldo I. Kenerson, E. W. Lane, F. J. Sanger, F. Knapp, and Charles H. Lee. 156.

"Lateral Earth and Concrete Pressures." Lazarus White and George Paaswell. (With Discussion.) 1685.

"Principles Applying to Highway Road-Beds." Ira B. Mullis. (With Discussion.) 1381.

SPILLWAYS.

"Siphons as Water-Level Regulators." J. C. Stevens. (With Discussion.) 1787.

STEAM POWER.

Heat generated energy. 1060.

Progress in the generation of energy by heat engines. 943.

STEEL PLATES.

"Pin-Connected Plate Links." Bruce G. Johnston. 314. Discussion: Harold D. Hussey. 337.

STREAM CONTAMINATION.

See **WATER POLLUTION.**

STRESS AND STRAIN.

"Design of Pile Foundations." C. P. Vetter. (With Discussion.) 758.

"Earthquake Stresses in an Arch Dam." Ivan M. Nelidov and Harold E. von Bergen. (With Discussion.) 133.

"Pin-Connected Plate Links." Bruce G. Johnston. (With Discussion.) 314.

STRUCTURES, THEORY OF.

"Mechanical Structural Analysis by the Moment Indicator." Arthur C. Ruge and Ernst O. Schmidt. 1659. Discussion: John B. Wilbur, William J. Eney, and Otto Gottschalk. 1672.

"Preliminary Design of Suspension Bridges." Shortridge Hardesty and Harold E. Wessman. (With Discussion.) 579.

"Relative Flexure Factors for Analyzing Continuous Structures." Ralph W. Stewart. (With Discussion.) 521.

"Solution of Equations in Structural Analysis by Converging Increments." George H. Dell. 1543. Discussion: A. Floris, L. E. Grinter, and A. A. Eremin. 1555.

SURVEYING.

"The Three-Point Problem in a Co-Ordinated Field." R. Robinson Rowe. (With Discussion.) 1314.

TIDAL POWER.

See **WATER POWER.**

TRADE WASTE.

Progress in industrial wastes control. 854.

TRAFFIC.

Definitions as proposed by a Committee of the Institute of Traffic Engineers. 441.

" Increasing the Traffic Capacity and Safety of Thoroughfares": A Symposium. Lewis W. McIntyre, Donald M. McNeil, Arnold H. Vey, and E. L. Schmidt. (With Discussion.) 440.

TRAILERS.

Trailers and mobile homes. 1576.

TRANSPORTATION.

" Motor Transportation—A Forward View": A Symposium. C. F. Kettering, Thomas H. MacDonald, and Leroy C. Smith. 1562. Discussion: F. Lavis, Edgar Dow Gilman, George Hartley, Robert Kingery, R. L. Morrison, Roy F. Bessey, Bruce D. Greenshields, Robert B. Brooks, H. George Altvater, and W. W. Crosby. 1597.

TRIANGULATION.

" The Three-Point Problem in a Co-Ordinated Field." R. Robinson Rowe. 1314. Discussion: Oscar S. Adams, George D. Whitmore, and John R. Jahn. 1325.

TRUSSES.

" Beam Constants for Continuous Trusses and Beams." George L. Epps (With Discussion.) 1522.

TURBINES (WATER).

Hydro-generation of energy. 952.

TURBULENCE.

" Laboratory Investigation of Flume Traction and Transportation." Y. L. Chang. (With Discussion.) 1246.

VALUATION.

Cost of energy generation—depreciation and obsolescence. 1127.

VIBRATION.

" Earthquake Stresses in an Arch Dam." Ivan M. Nelidov and Harold E. von Bergen. (With Discussion.) 133.

" Natural Periods of Uniform Cantilever Beams." Lydik S. Jacobsen. (With Discussion.) 402.

WATER.

" Water-Softening Plant Design." W. H. Knox. 1425. Discussion: Philip Burgess, A. Elliott Kimberly, L. R. Howson, Charles P. Hoover, M. H. Klegerman, Rollin F. MacDowell, and D. E. Davis. 1436.

WATER, FLOW OF, IN OPEN CHANNELS.

" A Theory of Silt Transportation." W. M. Griffith. (With Discussion.) 1733.

" Energy Mass Diagrams for Power Studies." John W. Hackney. (With Discussion.) 1644.

" Laboratory Investigation of Flume Traction and Transportation." Y. L. Chang. (With Discussion.) 1246.

" Observed Effects of Geometric Distortion in Hydraulic Models." Kenneth D. Nichols. (With Discussion.) 1488.

WATER, FLOW OF, IN PIPES.

"Economic Pipe Sizes for Water Distribution Systems." Thomas R. Camp. (With Discussion.) 190.

"Relation of Rainfall and Run-Off to Cost of Sewers." John A. Rousculp. 1473.

"Transportation of Sand and Gravel in a Four-Inch Pipe." G. W. Howard. (With Discussion.) 1334.

"Water-Hammer Pressures in Compound and Branched Pipe." Robert W. Angus. (With Discussion.) 340.

WATER, FLOW OF, THROUGH ORIFICES.

"Siphons as Water-Level Regulators." J. C. Stevens. (With Discussion.) 1787.

WATER HAMMER.

"Water-Hammer Pressures in Compound and Branched Pipe." Robert W. Angus. 340. Discussion: K. J. DeJuhasz, Harold A. Thomas, F. Knapp, Martin A. Mason and Pierre F. Danel and Antoine Craya, and A. A. Kalinske. 377.

WATER LAWS.

"Interstate Water Problems." Final Report of the Committee of the Irrigation Division on Interstate Water Rights. 1822.

WATER METERS.

See **METERS.**

WATER POLLUTION.

"Deoxygenation and Reoxygenation." C. J. Velz. (With Discussion.) 560.

Planning for pollution control at Pittsburgh, Pa. 860.

"Stream Pollution in the Ohio River Basin": A Symposium. George E. Barnes, Harold W. Streeter, Charles E. Ryder, W. L. Stevenson, E. S. Tisdale, D. E. Davis, J. E. Root, and Abel Wolman. 812. Discussion: D. E. Davis, L. S. Morgan, C. A. Holmquist, Robert Spurr Weston, Karl Imhoff, Henry D. Johnson, Jr., Charles M. Reppert, Edwin K. Morse, James LeVan, John C. H. Lee, W. H. Wisely, F. C. Dugan, G. M. Ridenour, Arthur W. Baum, Jr., G. R. Scott, and Don E. Bloodgood. 878.

Stream pollution problems at Cincinnati, Ohio. 868.

WATER POWER.

Characteristics and costs of hydro-electric plants. 1099.

Economic value of the Conowingo water power in the Philadelphia electric system. 1121.

"Energy Mass Diagrams for Power Studies." John W. Hackney. 1644. Discussion: Edgar E. Foster, and Lyle A. Whitsit. 1654.

Hydro-generation of energy. 952, 1088.

Passamaquoddy tidal power project. 670, 691.

Power in the northwest. 674.

WATER PRESSURES.

"Siphons as Water-Level Regulators." J. C. Stevens. (With Discussion.) 1787.

"Water-Hammer Pressures in Compound and Branched Pipe." Robert W. Angus. (With Discussion.) 340.

WATER RIGHTS.

"Interstate Water Problems." Final Report of the Committee of the Irrigation Division on Interstate Water Rights. 1822.

WATER SOFTENING.

See **WATER.**

WATER STORAGE.

"Energy Mass Diagrams for Power Studies." John W. Hackney. (With Discussion.) 1644.

"Flood Routing." Edward J. Rutter, Quintin B. Graves, and Franklin F. Snyder. (With Discussion.) 275.

WATER WORKS.

"Water-Softening Plant Design." W. H. Knox. (With Discussion.) 1425.

WHARVES.

"Reconstruction of a Pier in Boston, Massachusetts, Harbor." Charles M. Spofford. 1625. Discussion: William G. Atwood, John N. Ferguson, and John Ayer. 1639.

WIND PRESSURES.

"Aerodynamics of the Perisphere and Trylon at World's Fair." Alexander Klemin, Everett B. Schaefer, and J. G. Beerer, Jr. (With Discussion.) 1449.

ZONING OF CITIES.

"Practical Methods of Re-Zoning Urban Areas." Hugh E. Young. 904. Discussion: Robert D. Kohn, Myron D. Downs, Harland Bartholomew, Benjamin Saltzman, and G. H. Herrold. 928.

AUTHOR INDEX

ADAMS, OSCAR S.
The three-point problem. 1325.

AGATZ, A.
Design of pile foundations. 795.

ALBERT, ODD.
Design of pile foundations. 784.

ALDERSON, ALGERNON BROWN.
Memoir of. 1871.

ALDRICH, ELLWOOD H.
Economic pipe sizes. 205.

ALLEN, C. FRANK.
Public works. 706.

ALLEN, WALTER HINDS.
Memoir of. 1872.

ALLIN, RAY L.
Earthquake stresses in an arch dam. 148.

ALLISON, JOSEPH CHESTER.
Memoir of. 1875.

ALLISON, WILLIAM NOEL.
Memoir of. 2054.

ALTVATER, H. GEORGE.
Motor transportation. 1619.

AMMANN, O. H.
Design of suspension bridges. 624.

ANGUS, ROBERT W.
"Water-Hammer Pressures in Compound and Branched Pipes." 340.

ARNESON, EDWIN PERCIVAL.
Memoir of. 1878.

ARNSTEIN, KARL.
Aerodynamics of perisphere and trylon. 1470.

ATWOOD, WILLIAM G.
Reconstruction of a harbor pier. 1639.

AUSTIN, ROBERT EDWARD.
Memoir of. 2055.

AYER, JOHN.
Reconstruction of a harbor pier. 1640.

AYRES, LOUIS E.
Public Works, 742.

BABB, CYRUS CATES.
Memoir of. 1881.

BACH, HERMANN.
Multiple-stage sewage sludge digestion. 125.

BAKER, DONALD M.
Public works. 720.

BANTA, A. PERRY.
" Multiple-Stage Sewage Sludge Digestion." 93.

BARNES, GEORGE E.
" Stream Pollution in the Ohio River Basin: A Symposium: Foreword." 814.

BARROWS, H. K.
" Cost of Energy Generation: Second Symposium on Power Costs: Hydro-Generated Energy." 1088.
" Final Report of the Committee of the Irrigation Division on Interstate Water Rights: Interstate Water Problems." 1822.
Public works. 727.

BARTHOLET, C. J.
" Final Report of the Committee of the Irrigation Division on Interstate Water Rights: Interstate Water Problems." 1822.

BARTHOLOMEW, HARLAND.
Re-zoning urban areas. 930.

BASS, FREDERIC.
Economics of sewage treatment. 1242.

BATCHELDER, CHARLES LELAND.
Memoir of. 1884.

BAUER, S. G.
A theory of silt transportation. 1768.

BAUM, ARTHUR W., JR.
Stream pollution. 897.

BAUMANN, PAUL.
Design of rock-fill dams. 39.

BAUSHER, CARMI IRVING.
Memoir of. 2023.

BEERER, J. G., JR.
" Aerodynamics of the Perisphere and Trylon at World's Fair." 1449.

BENNETT, RALPH.
Economics of energy generation. 1015.

BENT, ARTHUR SAMUEL.
    Memoir of. 2056.

BESSEY, ROY F.
    Motor transportation. 1609.
    Public works. 713.

BIRBECK, RICHARD.
    Memoir of. 1886.

BLANEY, HARRY F.
    A theory of silt transportation. 1754.

BLOG, LEON.
    Design of suspension bridges. 626.
    Flexure factors for continuous structures. 542.

BLOODGOOD, DON E.
    Stream pollution. 901.

BOGART, JOHN ALLEYNE CALHOUN.
    Memoir of. 2023.

BOGERT, CLINTON L.
    Economic pipe sizes. 203.

BONBRIGHT, JAMES C.
    Cost of energy generation. 1192.

BROOKS, ROBERT B.
    Motor transportation. 1616.

BROWN, FRED R.
    Transportation of sand and gravel. 1349.

BUCK, HENRY ROBINSON.
    Memoir of. 1888.

BURGESS, PHILIP.
    Water-softening plant design. 1436.

BURMISTER, DONALD M.
    Mechanical analyses of soils. 156.

BURNELL, W. V.
    Cost of energy generation. 1153.

BYRNE, EDWARD ABRAHAM.
    Memoir of. 1890.

CALDWELL, FRED EDWARD.
    Memoir of. 1893.

CAMP, CECIL S.
    Flood routing. 295.

CAMP, THOMAS R.
" Economic Pipe Sizes for Water Distribution Systems." 190.
Grit chamber model tests. 232.

CAMPBELL, FRANK B.
" Graphical Representation of the Mechanical Analyses of Soils." 150.

CAMPEN, W. H.
Highway road-beds. 1403.

CAREY, HAROLD NEVIN.
Traffic problems. 506.

CARROLL, JAMES EDWARD.
Memoir of. 1894.

CASEY, FORREST McKENDREE.
Memoir of. 2025.

CHANG, Y. L.
" Laboratory Investigation of Flume Traction and Transportation." 1246.

CHRISTIANSEN, J. E.
A theory of silt transportation. 1757.
Flume traction. 1293.

CHRISTIE, A. G.
Cost of energy generation. 1160.

CHRISTIE, GEORGE B.
Memoir of. 1896.

CLARK, C. S.
" Final Report of the Committee of the Irrigation Division on Interstate Water Rights: Interstate Water Problems." 1822.

COAN, JOHN M., JR.
Design of pile foundations. 792.

COLLINS, WILLIAM T.
Flood routing. 302.

CORWIN, T. J., JR.
Water-level regulators. 1807.

CRAYA, ANTOINE.
Water-hammer pressures. 391.

CROOK, JOHN ANTHONY.
Memoir of. 2026.

CROSBY, W. W.
Motor transportation. 1620.
Traffic problems. 507.

CROSS, HARDY.
Design of suspension bridges. 617.

CROZIER, BERNARD LABROQUERE.
Memoir of. 1898.

CRUISE, EDGAR DUDLEY.
Memoir of. 1899.

CUMMINGS, A. E.
Lateral earth and concrete pressures. 1701.

CUMMINGS, NOAH.
Memoir of. 2028.

CURRIN, H. P.
Water-level regulators. 1803.

DALE, F. A.
Economics of energy generation. 1036.

DANEL, PIERRE F.
Transportation of sand and gravel. 1372.
Water-hammer pressures. 391.

DAVIS, BENJAMIN HERMAN.
Memoir of. 1901.

DAVIS, D. E.
Stream pollution. 878.
"Stream Pollution in the Ohio River Basin: A Symposium: Planning for Pollution Control at Pittsburgh, Pennsylvania." 860.
Water-softening plant design. 1447.

DAVIS, RALPH GRAY.
Memoir of. 1902.

DEANS, C. W.
Beam constants. 1530.

DeJUHASZ, K. J.
Water-hammer pressures. 377.

DELL, GEORGE H.
"Solution of Equations in Structural Analysis by Converging Increments." 1543.

DENT, ELLIOTT J.
Public works. 705.
Transportation of sand and gravel. 1351.

DERRICK, CLARENCE.
Memoir of. 2031.

DINGLE, JAMES HERVEY.
Memoir of. 1904.

DOBBINS, JOHN LESLIE.
Memoir of. 2032.

DOWNS, MYRON D.
Re-zoning urban areas. 928.

DREYER, WALTER.
Design of rock-fill dams. 53.

DREYFUS, EDWIN D.
Cost of energy generation. 1200.

DUGAN, F. C.
Stream pollution. 894.

DUREPAIRE, M. P.
Transportation of sand and gravel. 1369.

EAST, L. R.
Design of rock-fill dams. 69.

EDDY, HARRISON PRESCOTT.
Memoir of. 1867.

EHRGOTT, HERBERT W.
Geometric distortion in hydraulic models. 1510.

ELLIOTT, LOUIS.
Cost of energy generation. 1166.

ENEY, WILLIAM J.
The moment indicator. 1676.

EPPS, GEORGE L.
" Beam Constants for Continuous Trusses and Beams." 1522.

EREMIN, A. A.
Analysis by converging increments. 1558.
Beam constants. 1537.
Design of pile foundations. 790.
Design of suspension bridges. 618.

FAHLQUIST, FRANK E.
Mechanical analyses of soils. 169.

FARIS, O. A.
A theory of silt transportation. 1756.

FARNHAM, CHARLES HENRY.
Memoir of. 2034.

FAY, FREDERIC H.
" Engineering Economics and Public Works: A Symposium: Advantages of Orderly Planning." 636.

FELD, JACOB.
Design of pile foundations. 791.
Lateral earth and concrete pressures. 1708.
Mechanical analyses of soils. 164.

FERGUSON, JOHN N.
Reconstruction of a harbor pier. 1639.

FIELD, JOHN E.
Design of rock-fill dams. 45.

FINCH, J. K.
Public works. 701.

FINLAY, W. S., JR.
Economics of energy generation. 1009.

FISCHER, A. W.
Design of suspension bridges. 609.
Earthquake stresses in an arch dam. 147.

FLACK, W. R.
Traffic problems. 509.

FLORIS, A.
Analysis by converging increments. 1555.
Design of rock-fill dams. 30.
Earthquake stresses in an arch dam. 143.
Flexure factors for continuous structures. 544.

FOLK, SAMUEL B.
Public works. 751.

FOLSOM, R. G.
Transportation of sand and gravel. 1359.

FOSTER, EDGAR E.
Energy mass diagrams. 1654.

FOWLER, FREDERICK H.
Design of rock-fill dams. 49.

FOX, HAROLD K.
Design of rock-fill dams. 28.

FREEMAN, RALPH E.
" Economic Aspects of Energy Generation: A Symposium: Social Implications of Technological Trends in the Power Industry." 995.

FURBER, PIERCE P.
Public works. 708.

GALLOWAY, J. D.
Public works. 734.
" The Design of Rock-Fill Dams." 1.

GELINEAU, VICTOR.
Memoir of. 1905.

GERDES, H. G.
Cost of energy generation. 1167.

GILMAN, EDGAR DOW.
Motor transportation. 1602.

GISIGER, PAUL E.
Economics of energy generation. 1034.

GLADFELTER, H. S.
Transportation of sand and gravel. 1374.

GOMEZ-PEREZ, FRANCISCO.
Design of rock-fill dams. 75.

GOODRICH, R. D.
Flood routing. 295.

GOTTSCHALK, OTTO.
The moment indicator. 1681.

GOULD, WILLIAM TILLOTSON.
Memoir of. 1908.

GRANDPRÉ, AMBROSE GOULET.
Memoir of. 1910.

GRAVES, QUINTIN B.
" Flood Routing." 275.

GRAY, BERNARD E.
Highway road-beds. 1405.

GRAY, JOHN HENRY.
Memoir of. 1911.

GREAVES-WALKER, A. F.
Highway road-beds. 1402.

GREENSHIELDS, BRUCE D.
Motor transportation. 1612.

GREIG, J. M. M.
Economic pipe sizes. 203.

GRIFFIN, A.
Water-level regulators. 1802.

GRIFFITH, JOHN HOWELL.
Memoir of. 1912.

GRIFFITH, W. M.
" A Theory of Silt Transportation." 1733.

GRIMES, EDWIN LINCOLN.
Memoir of. 1915.

GRINTER, L. E.
Analysis by converging increments. 1556.

GRUNSKY, CARL EWALD, JR.
Memoir of. 1916.

HACKNEY, JOHN W.
"Energy Mass Diagrams for Power Studies." 1644.

HADLEY, HOMER M.
Flexure factors for continuous structures. 536.

HALL, D. B.
Flexure factors for continuous structures. 545.

HALSEY, MILO CLINTON.
Memoir of. 2035.

HANNA, F. W.
Earthquake stresses in an arch dam. 144.

HANSEN, HANS JORGEN.
Memoir of. 1919.

HARDESTY, SHORTRIDGE.
"Preliminary Design of Suspension Bridges." 579.

HART, SAMUEL ALEXANDER.
Memoir of. 2037.

HARTLEY, GEORGE.
Motor transportation. 1605.

HARTMAN, ALFRED HANSON.
Memoir of. 1920.

HARZA, L. F.
Design of rock-fill dams. 39.

HATCH, JAMES NOBLE.
Memoir of. 1923.

HAZELTON, CHARLES WILLIAM.
Memoir of. 1924.

HEATLEY, THOMAS.
Memoir of. 1931.

HEDRICK, IRA GRANT.
Memoir of. 1932.

HENDRICKS, VICTOR KING.
Memoir of. 1935.

HENNES, ROBERT G.
Lateral earth and concrete pressures. 1704.

HENRY, PHILIP W.
Public works. 726.

HERROLD, G. H.
Re-zoning urban areas. 936.

HESS, EDWIN WESLEY.
Memoir of. 1937.

HEUKELEKIAN, H.
Multiple-stage sewage sludge digestion. 122.

HILDER, FRAZER CROSWELL.
Memoir of. 1938.

HILL, HIBBERT M.
Design of pile foundations. 779.

HILL, H. N.
Battle-deck floor systems. 267.

HINCKLEY, HERBERT McDONALD.
Memoir of. 2038.

HINDERLIDER, M. C.
"Final Report of the Committee of the Irrigation Division on Interstate Water Rights: Interstate Water Problems." 1822.

HIRASHIMA, K. BERT.
Natural periods of cantilever beams. 432.
Public works. 741.

HIRSHFELD, C. F.
"Cost of Energy Generation: Second Symposium on Power Costs: Heat-Generated Energy." 1060.

HOLMES, GLENN W.
A theory of silt transportation. 1764.

HOLMQUIST, C. A.
Stream pollution. 882.

HOOVER, CHARLES P.
Water-softening plant design. 1441.

HOUSNER, GEORGE W.
Flexure factors for continuous structures. 534.

HOWARD, G. W.
A theory of silt transportation. 1752.
"Transportation of Sand and Gravel in a Four-Inch Pipe." 1334.

HOWLAND, W. E.
Grit chamber model tests. 240.

HOWSON, GEORGE W.
Design of rock-fill dams. 42.

HOWSON, L. R.
Water-softening plant design. 1440.

HUANG, W. H.
Flume traction. 1297.

HUBBELL, GEORGE E.
"Grit Chamber Model Tests for Detroit, Michigan, Sewage Treatment Project." 214.

HUBER, WALTER L.
Design of rock-fill dams. 33.

HULBURD, LUCIUS SANFORD.
Memoir of. 2040.

HUSSEY, HAROLD D.
Pin-connected plate links. 337.

HUTCHINSON, RALPH W.
Flexure factors for continuous structures. 546.

HYATT, EDWARD.
" Final Report of the Committee of the Irrigation Division on Interstate Water Rights: Interstate Water Problems." 1822.

HYDE, CHARLES GILMAN.
Economics of sewage treatment. 1239.

IMHOFF, KARL.
Stream pollution. 885.

INGLIS, C. C.
A theory of silt transportation. 1769.

INGRAM, EDWARD LOVERING.
Memoir of. 1940.

JACKSON, JOHN FRANKLIN.
Memoir of. 2042.

JACOBSEN, LYDIK S.
" Natural Periods of Uniform Cantilever Beams." 402.

JACOBUS, D. S.
Economics of energy generation. 1041.

JACOBY, HURLBUT SMITH.
Memoir of. 1941.

JAHN, JOHN R.
The three-point problem. 1328.

JANNI, ALFREDO CARLO.
Memoir of. 1944.

JARRETT, EDWIN SETON.
Memoir of. 1945.

JARVIS, C. S.
Design of rock-fill dams. 66.

JENKINS, JENKS BUFFUM.
Memoir of. 1949.

JENNINGS, FRANK WASHBURN.
Memoir of. 1952.

JEWETT, JOHN YOUNG.
Memoir of. 2044.

JINICH, MIGUEL.
Design of rock-fill dams. 75.

JOHNSON, HENRY D., JR.
Stream pollution. 885.

JOHNSON, JOE W.
Flume traction. 1287.
A theory of silt transportation. 1749.

JOHNSTON, BRUCE G.
" Pin-Connected Plate Links." 314.

JONES, JONATHAN.
Battle-deck floor systems. 272.

JUSTIN, JOEL D.
Cost of energy generation. 1149.
" Economic Aspects of Energy Generation: A Symposium: Improvements in the Utilization of Energy." 971.
Mechanical analyses of soils. 165.

KADIE, CARL H., JR.
Mechanical analyses of soils. 159.

KALINSKE, A. A.
Water-hammer pressures. 395.

KAROL, JACOB.
Design of suspension bridges. 610.

KEEFER, C. E.
Multiple-stage sewage sludge digestion. 128.

KELLY, HUGH A.
Traffic problems. 502.

KENERSON, WALDO I.
Mechanical analyses of soils. 169.

KETTERING, C. F.
" Motor Transportation—A Forward View: A Symposium: Joint Responsibility of the Automotive and the Civil Engineer." 1563.

KIMBERLY, A. ELLIOTT.
Water-softening plant design. 1437.

KING, HENRY R.
Water-level regulators. 1808.

KINGERY, ROBERT.
Motor transportation. 1606.

KLEGERMAN, M. H.
Economic pipe sizes. 207.
Water-softening plant design. 1443.

KLEMIN, ALEXANDER.
" Aerodynamics of the Perisphere and Trylon at World's Fair." 1449.

KLEMPERER, W. B.
Aerodynamics of the perisphere and trylon. 1471.

KNAPP, F.
Cost of energy generation. 1205.
Design of rock-fill dams. 64.
Economics of energy generation. 1039.
Economic pipe sizes. 209.
Mechanical analyses of soils. 178.
Water-hammer pressures. 388.

KNAPP, GEORGE S.
" Final Report of the Committee of the Irrigation Division on Interstate Water Rights: Interstate Water Problems." 1822.

KNAPPEN, T. T.
Mechanical analyses of soils. 163.

KNOX, W. H.
" Water-Softening Plant Design." 1425.

KOHN, ROBERT D.
Re-zoning urban areas. 928.
